CHEMICAL PROPERTIES OF SELECTED MADISON COUNTY, VIRGINIA, SOILS

D. E. Pettry, J. H. Elder, Jr., J. R. Grove^a

INTRODUCTION

Bounded on the north by Rappahannock County, on the east by Culpeper County, on the west by Page County, and on the south by Orange and Green Counties, historic Madison County comprises about 327 square miles of north central Virginia. Madison, the county seat, situated near the center of the county, is located about 70 miles northwest of Richmond and 75 miles southwest of Washington, D. C. Madison County was formed in 1793 from Culpeper County and named for James Madison, fourth President of the United States. The county had a population of 8,638 persons according to the 1970 census. Forest and farm woodland comprise about 60 percent of the county while about 40 percent is cleared and used for crops and pasture.

A soil survey of Madison County was completed in 1965 by the Virginia Agricultural Experiment Station in cooperation with Madison County and the Soil Conservation Service. "Soils of Madison County, Virginia", a comprehensive report, was published in 1965 and widely distributed in the county. In addition to the soils report, soil maps with a scale of 1" = 600' are available in the Agricultural Extension Office. The national Soil Survey Report containing maps is in the publication process.

^aAssociate Professor, Assistant Professor, and Madison County Extension Agent. Agronomy Department, Virginia Polytechnic Institute and State University.

During the soil survey, soil scientists examined the soils and underlying materials in a systematic fashion in order to classify the soils and to make interpretations for multi-purpose soil usage. The soils were described and the distinguishing characteristics were recorded in a standard manner. Samples were taken from typical soils occurring extensively in the county in order to determine the characteristic chemical properties by laboratory analyses. Chemical properties of the common soils of Madison County are presented in this report.

Geographical Setting

Madison County lies within the Piedmont and the Blue Ridge physiographic provinces. Elevations range from 298 feet at the junction of the Robertson (Robison) and Rapidan Rivers to 4,049 feet at the summit of Hawksbill Mountain (1, 3). About 70 percent of the county is located in the Piedmont province, which is characterized by gently to strongly sloping relief with random steep areas. The Blue Ridge province comprises the western part of the county and it accounts for about 30 percent of the total land area in the county. This area ranges from moderately steep to very steep with elevations ranging from about 1,000 to 4,000 feet above mean sea level. Soils of this area are generally rocky.

The rocks of Madison County, which serve as parent materials for soil formation, consist of igneous, sedimentary, and metamorphic types. Seven major geologic formations occur in the county. Rocks of the Piedmont province are dominantly metamorphosed and those of both igneous and sedimentary origin occur. They consist of granite gneisses, mica schists, and phyllites with smaller areas of greenstone schists, sandstone conglomerates, and shale (1,5).

Rocks of the Blue Ridge province are primarily metamorphosed rocks of igneous origin. They consist of greenstone schist, granodiorites, granites, and granite gneisses with small inclusions of sandstone (1, 5).

Soil Morphology

Soils comprise the surface landscape of the earth's outer crust. These natural bodies result from the weathering actions of climate, organisms, and relief on parent materials over a period of time. Since soils are natural bodies, they may occur as discrete individuals, but they are often mixed and interwoven into complicated patterns. Adjacent soils are often linked by broad transition zones.

The soils of Madison County are quite complex and they occur in intricate patterns of the landscape. Approximately 350 individual soil units were delineated in the Madison County soil survey (2). Each of these soil units differs in some manner from the others. The forces of gravity and water acting on complex parent materials have had a dominant influence on soil formation in the county. These forces have contributed to weathering and movement of parent materials resulting in development of transported soils at lower elevations. Many of the soils along the base of the Blue Ridge regions of the county have formed in materials moved downslope by the forces of gravity. Flooding waters from the Hughes, Robertson (Robinson), Rapidan, and Conway Rivers have eroded and deposited materials.

A hypothetical soil profile having all the principal horizons is presented in Figure 1. Few soils contain all the horizons exhibited by the hypothetical profile.

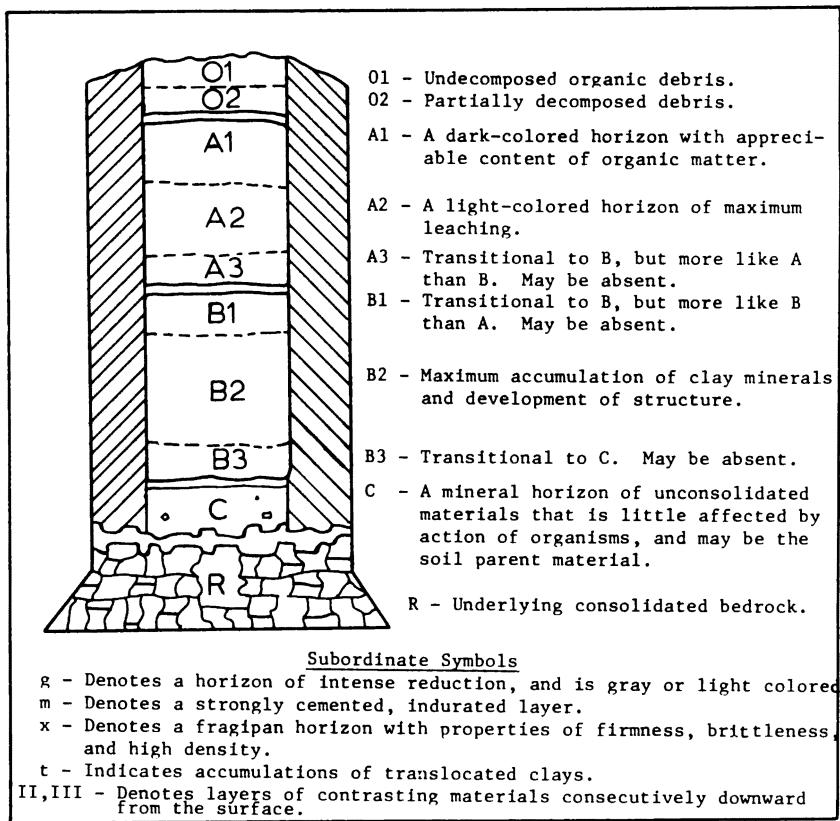

Fig. 1 - Hypothetical Soil Profile with all the Principal Horizons.

The soils of Madison County are essentially a mixture of inorganic particles with relatively small amounts of decaying organic matter. The various particle-size groups (sand, silt, clay) vary widely and proportions of the groups (textural classes) are defined in the glossary. Physical properties of sand, silt, and clay differ considerably. Uncoated sand particles are rather inert, and they exhibit little cohesion or plasticity. In contrast, clay particles are reactive and highly cohesive and plastic. Clays also have high water-holding capacity, and retard movement of air and water. Silt particles are intermediate to sands and clays.

Chemical Properties

Soil chemical properties in combination with other features such as permeability, structure, texture, and consistency largely determine the limitations and potential of an individual soil. Chemical properties are not evident in visual observations of a soil and laboratory analyses are necessary to define these characteristics. The amount and type of clay minerals present and the organic matter content largely regulate the chemical nature of soils. These substances have the capacity to attract and hold cations. Many cations are essential plant nutrients.

Calcium, magnesium, and potassium are the major non-acidic exchangeable cations in soils. The cations on the soil exchange complexes are in dynamic equilibrium with the soil solution. When non-acidic cations are removed by plants or organisms, aluminum and hydrogen ions may replace them on the exchange site. Since aluminum and hydrogen act as acids, the exchangeable hydrogen (reported in Table 1) actually includes both hydrogen and aluminum. The exchangeable aluminum is presented in a separate column in Table 1.

The cations are reported in units of milli-equivalents, which is defined as one milligram of hydrogen or the amount of any other ion that will combine with or displace it. The unit can be converted to pounds per acre on the basis that an acre of soil (about 6 inches deep) weighs approximately 2,000,000 pounds. One milli-equivalent per 100 grams of soil is equivalent to 942 pounds of potash (K_2O) or 1,000 pounds of limestone ($CaCO_3$) per acre furrow slice. The total exchangeable cations is equal to the cation exchange capacity of the soil.

Soil pH is a measure of the active soil acidity or basicity. It is defined as the logarithm of the reciprocal of the H-ion concentration

($\text{pH} = \log 1/\text{[H}^+\text{]}$). In acid solutions the pH is always less than 7, and in an alkaline solution, it is greater than 7. The following descriptive designations are commonly used to express pH values.

| | pH |
|----------------------------------|------------|
| Extremely acid | Below 4.5 |
| Very strongly acid | 4.5 to 5.0 |
| Strongly acid | 5.1 to 5.5 |
| Medium acid | 5.6 to 6.0 |
| Slightly acid | 6.1 to 6.5 |
| Neutral | 6.6 to 7.3 |
| Mildly alkaline | 7.4 to 7.8 |
| Moderately alkaline | 7.9 to 8.4 |
| Strongly alkaline | 8.5 to 9.0 |
| Very strongly alkaline | 9.1+ |

Since the pH scale is logarithmic, the extent of acidity or basicity does not occur in equal increments. For example, a soil at pH 5 has 10 times as much acidity as one at pH 6, while a soil at pH 4 has 100 times more acidity than the pH 6 soil. Soil pH levels have an important relationship on the solubility of plant nutrients. Extreme pH levels give rise to severe corrosion of metallic and concrete objects in contact with the soil.

Truog phosphorus, a dilute acid soluble phosphorus, is an estimate of the amount of phosphorus readily available to plants in acid soils. Generally, 25 parts per million (ppm) is adequate for many common crops and plants.

Methods of Analyses - Extractable acidity, bases, and organic matter content were determined using modified procedure of Peech (4). Available phosphorus was determined via the Truog procedure (6) using a Klett-Summerson Photoelectric Colorimeter. Soil pH was determined in 1:2 soil-water mixture employing a Beckman Zeromatic pH meter. Exchangeable (KCl) aluminum was determined via modified Yuan procedure (7).

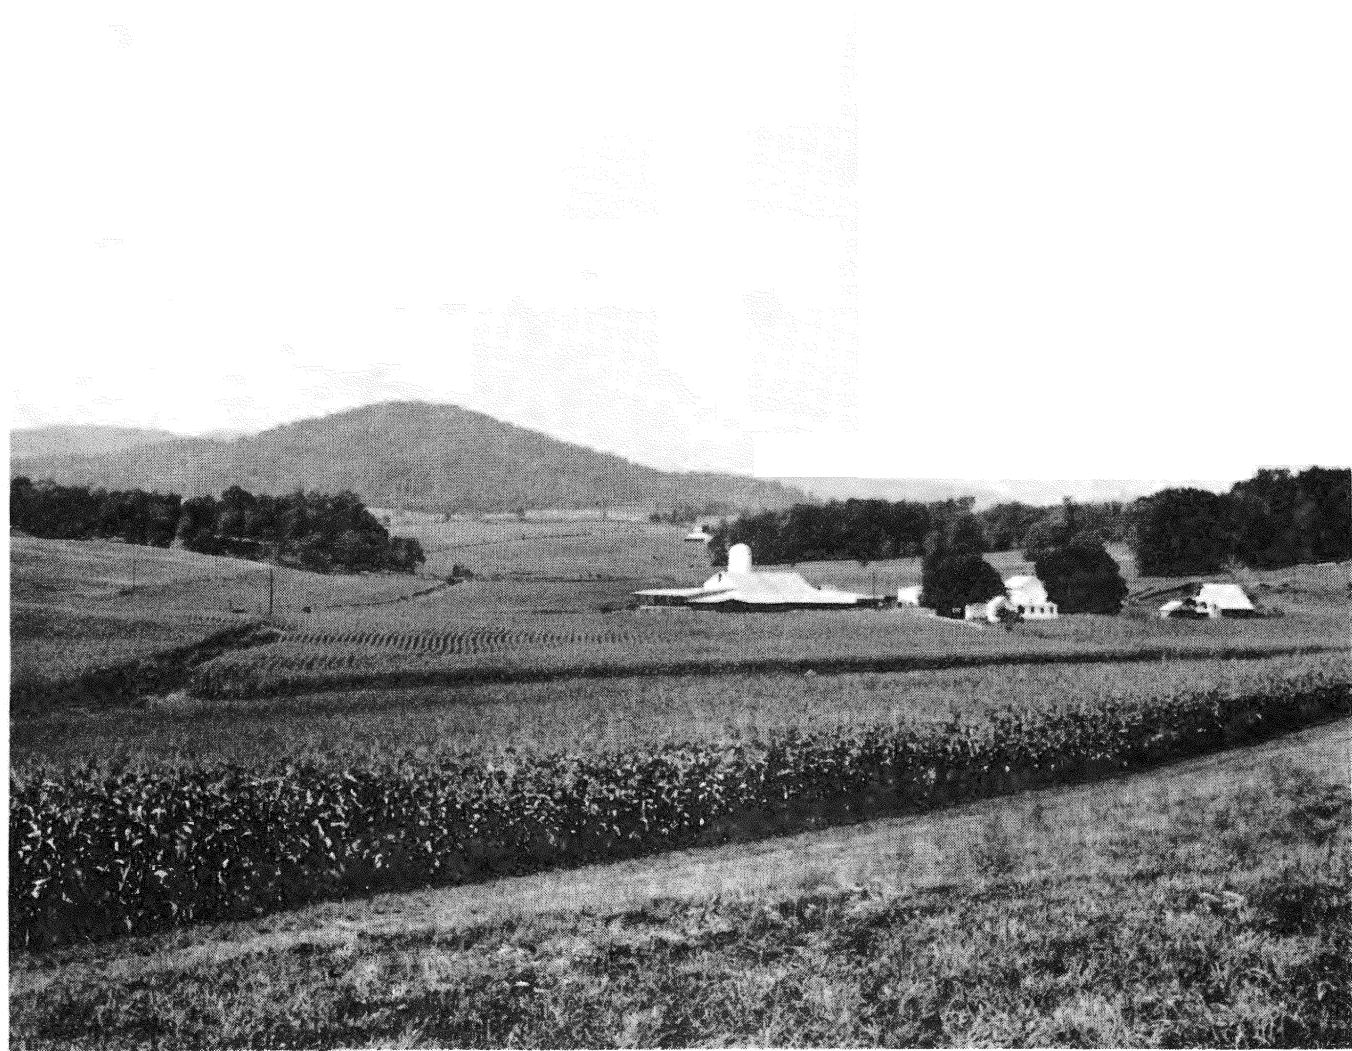

Photo 1. Good conservation practices using the Chewacla, Congaree, and Starr soils in continuous corn, and reserving the upland soils, Lloyd, Brandywine, Chester, and Eubanks in permanent pasture and hay crops.

Photo 2. A new soil is born - Parent material, residuum from granite rock, accumulates in crevice. Grass seeds sprout and grow, stabilizing the material from erosion, and if successful, the slow, intricate process to soil maturity is begun.

Photo 3. Continuous corn rotation on Chewacla soils - 187 bushels of corn per acre were harvested from this field in 1965.

Photo 4. Soil materials along with boulders and other rock fragments washed and rolled from mountain uplands to form colluvial soils in the valleys. The soil is naturally fertile and productive but tillage with normal machinery is impractical due to stone content. These soils are excellent for yellow poplar forest and they are suited to native Bluegrass pasture.

Photo 5. Extremely stony riverwash located on flood plains - unsuited to cropland and forest due to cobble and gravel content. Little fine soil material was originally deposited or otherwise it was moved downstream by flood waters.

Photo 6. Rolling landscape of Lloyd, Eubanks, Brandywine, Hiwassee, and Meadowville soils are typical of a large portion of Madison County.

Photo 7. Brandywine, Chester, and Meadowville soils are well suited to native Bluegrass pastures. Note the late summer drough effects on the Brandywine soil in the upper left corner of the photo.

Photo 8. Stony Brandywine soils on steep slopes are productive as native Bluegrass pasture lands. Small areas of Chester and Meadowville soils make good garden areas.

GLOSSARY

Alluvium - Sediments deposited on existing land surfaces by flowing water.
The materials are usually mixed or stratified.

Arkosic Sandstone - A sandstone containing appreciable amounts of feldspar.

Base Saturation % - The sum or total of the bases on the soil exchange sites divided by the exchangeable acidity multiplied by 100.

Coarse Fragment - Particles that exceed 2 mm in diameter.

Colluvium - Material which has moved downhill and has accumulated on lower slopes and at the bottom of hills.

Foot Slopes - Sloping areas occurring at the base of higher-lying areas, often referred to as "toe-slopes" when they occur at the end of a ridge.

Gneiss - A banded metamorphic rock with alternating layers of light colored quartz and feldspar and dark colored materials including mica and hornblende.

Granite - Granular rocks composed chiefly of feldspar and quartz, but usually contain mica and some ferromagnesium mineral.

Granodiorite - A granitic rock in which the feldspar portion is chiefly plagioclase or soda-line feldspar, usually containing a higher percentage of dark minerals such as biotite and hornblende.

Greenstone - A basic rock of igneous origin containing considerable epidote, a hydrous calcium aluminum iron silicate.

Horizons - Soil layers resulting from soil formation processes.

Parent Material - Partially weathered rock materials from which soils developed.

Phyllite - A metamorphic rock with finer banding than schist, intermediate between slate and schist.

Schist - A metamorphic rock with distinct cleavage.

Soil Separate - A group of soil particles separated on the basis of size.

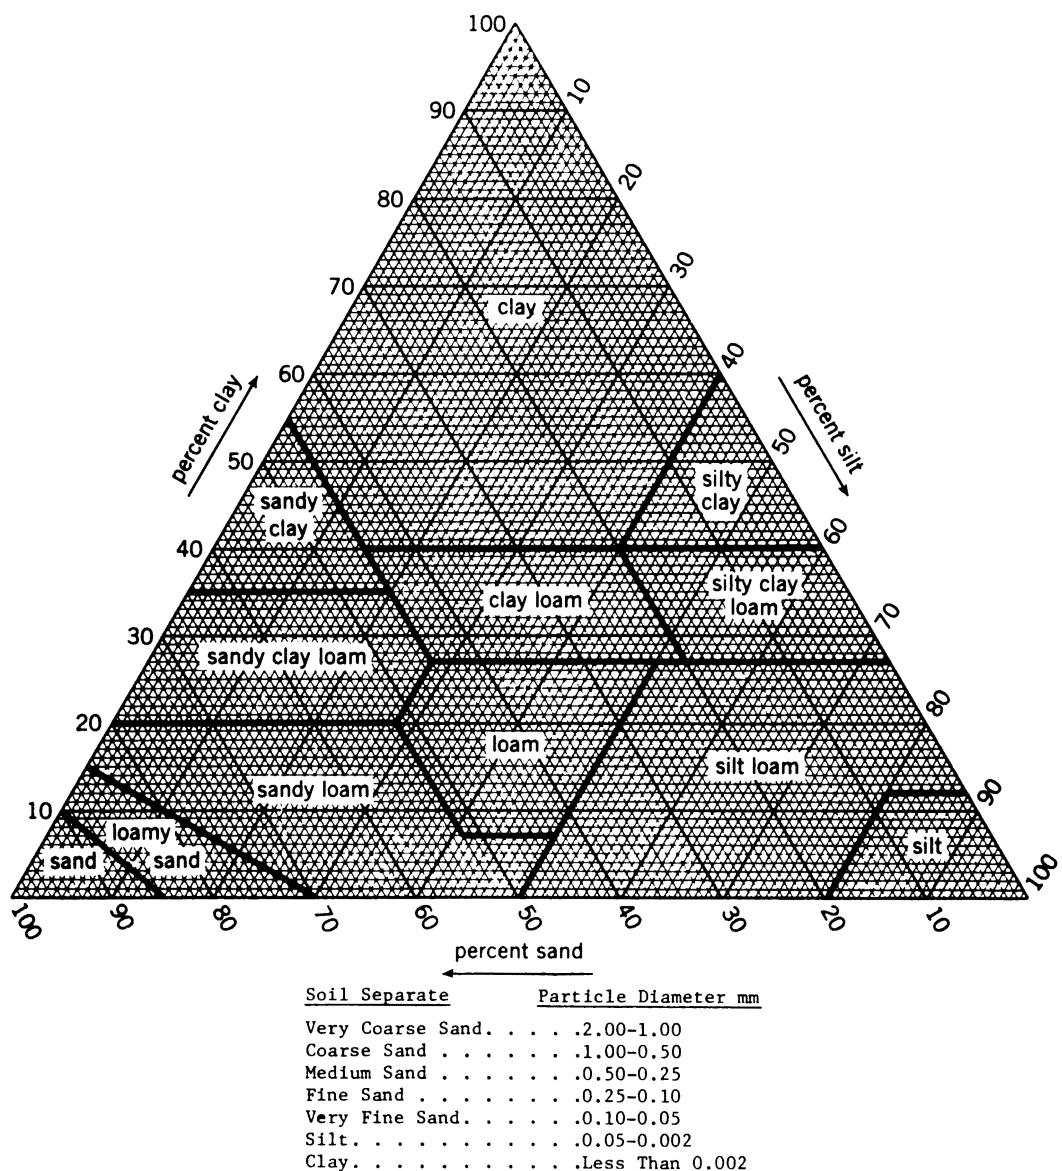

(USDA SYSTEM)

| <u>Soil Separate</u> | <u>Particle Diameter mm</u> |
|----------------------|-----------------------------|
| Very Coarse sand | 2.00-1.00 |
| Coarse Sand | 1.00-0.50 |
| Medium Sand | 0.05-0.25 |
| Fine Sand | 0.25-0.10 |
| Very Fine Sand | 0.10-0.05 |
| Coarse Silt | 0.05-0.005 |
| Fine Silt | 0.005-0.002 |
| Clay | Less than 0.002 |

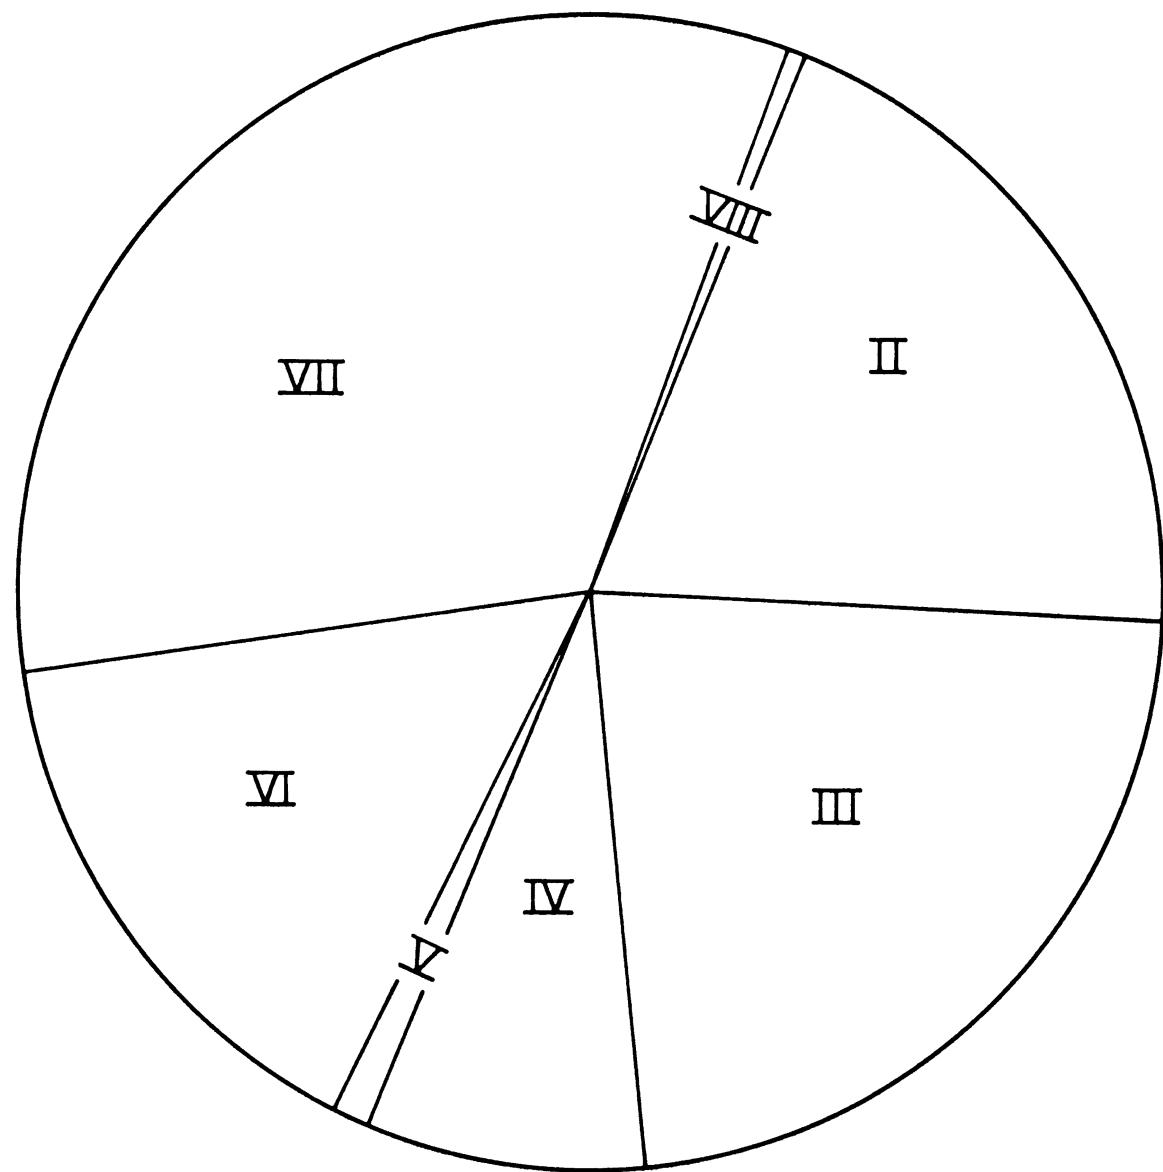

Terrace (stream) - An intermediate to high level area of alluvially deposited soil material.

Texture - A soil class based on the relative proportions of sand, silt, and clay size particles.
