## PREFACE

The term "multicomponent mass transport," as used here refers to those physical processes whereby molecular species in a mixture are caused to move relative to one another. By such processes a change in composition can be brought about.

For example, consider a sample of water containing a pollutant, say a dissolved pesticide. Suppose that a portion of this aqueous solution is forced through a suitable porous membrane by the use of pressure. In general, the membrane is more easily penetrated by the small water molecules than by the larger molecules of pesticide. Thus, the effluent from the low pressure side of the membrane will contain a very much reduced pesticide concentration. Therefore, it is possible to extract potable water from a contaminated source through use of a pressure difference and a suitable membrane. The rate and efficiency of this and similar processes is determined by the rates of mass transfer across a multicomponent system consisting of water, pesticide, and the membrane matrix. It is to the quantitative prediction of the rates and efficiencies of such multicomponent mass transfer operations that this work is addressed.

Processes involving such multicomponent mass transport are found throughout the water resource field. For example, the kinetics and efficiency of membrane desalination processes are governed by rates of mass transport. Similar membrane processes have been proposed for use in contaminate removal from a wide variety of industrial waste disposal streams. Another example are those processes in which rates of oxygen transfer into natural bodies of water is an important parameter in pollution control.

This project has been concerned with mass transport in aqueous and membrane systems. The objective has been to develop the underlying theory and to propose and test practical, quantitative models for the rates of mass transport in such systems. The quantitative information developed should prove invaluable in the engineering and control of pollution control processes.

William R. Walker

# MULTICOMPONENT MASS TRANSPORT <br> IN AQUEOUS AND MEMBRANE <br> SYSTEMS 

## Project Objectives

The basic objective of this study has been to develop and critically test models for multicomponent mass transport in aqueous and membrane systems. More specifically, this basic aim has been pursued through the following set of sub-objectives:
(1) Selecting a set of aqueous systems for detailed study followed by a comprehensive literature review to collect all pertinent data for the selected systems.
(2) Measuring multicomponent mass transport data in a selected system over a wide range of compositions.
(3) Developing a general mathematical model for multicomponent mass transport
(4) Obtaining optimum parameters for the mass transport models developed in (3).
(5) Determining whether the effective water of hydration of solutes in aqueous solutions can be reasonably determined as that value giving the best fit of the experimental transport data.
$\underline{\text { Summary of Research Procedures }}$

## System Selection and Literature Review

The transport phenomena selected for study were diffusion, electrical conductivity, and transport number. The systems selected for detailed study were those formed from the ions $\mathrm{H}^{+}, \mathrm{Na}^{+}, \mathrm{Cl}^{-}$, $\mathrm{NO}_{3}{ }^{-}$, and water, $\mathrm{H}_{2} \mathrm{O}$. The possible binary and ternary systems are as follows:

| Binary Systems |  |
| :--- | :--- |
| $\mathrm{NaCl}_{2}-\mathrm{H}_{2} \mathrm{O}$ | Ternary Systems |
| $\mathrm{HNO}_{3}-\mathrm{H}_{2} \mathrm{O}$ | $\mathrm{HCl}-\mathrm{HNO}_{3}-\mathrm{H}_{2} \mathrm{O}$ |
| $\mathrm{NaNO}_{3}-\mathrm{H}_{2} \mathrm{O}$ | $\mathrm{HCl}-\mathrm{NaCl}-\mathrm{H}_{2} \mathrm{O}$ |
| $\mathrm{HCl}-\mathrm{HNO}_{3}$ | $\mathrm{NaCl}-\mathrm{NaNO}_{3}-\mathrm{H}_{2} \mathrm{O}$ |
|  | $\mathrm{HNO}_{3}-\mathrm{NaNO}_{3}-\mathrm{H}_{2} \mathrm{O}$ |
|  |  |
|  | $\mathrm{NaCl}^{-\mathrm{HNO}} 33-\mathrm{H}_{2} \mathrm{O}$ |
|  | $\mathrm{NaNO}_{3}-\mathrm{HCl}-\mathrm{H}_{2} \mathrm{O}$ |

A survey of the transport data for such systems is given in Table (1). The numbers in the table are those of the references listed in the bibliography.

## Theoretical Considerations and Numerical Procedures

For analysis, the data were divided into binary and ternary systems. A numerical procedure was then developed to extract optimum parameters from the transport data for each system.

## Objective Function Selection

The optimum parameters for each binary system were defined as those which minimized the following objective function:

Sum Squares of Errors

$$
\begin{equation*}
=\sum_{\text {data }}\left(1-\mathrm{D}_{\mathrm{e}} / \mathrm{D}_{\mathrm{p}}\right)^{2}+\left(1-\mathrm{k}_{\mathrm{e}} / \mathrm{k}_{\mathrm{p}}\right)^{2}+\left(1-\mathrm{t}_{\mathrm{e}}^{+} / \mathrm{t}_{\mathrm{p}}^{+}\right)^{2} \tag{1}
\end{equation*}
$$

where: $\quad D_{\mathrm{e}}=$ experimental diffusion coefficients

$$
\begin{aligned}
& \mathrm{D}_{\mathrm{p} .}=\text { predicted diffusion coefficients } \\
& \mathrm{k}_{\mathrm{e}}=\text { experimental electrical conductivity } \\
& \mathrm{k}_{\mathrm{p}}=\text { predicted electrical conductivity } \\
& \mathrm{t}_{\mathrm{e}}^{+}=\text {experimental cation transport number } \\
& \mathrm{t}_{\mathrm{p}}^{+}=\text {predicted cation transport number }
\end{aligned}
$$

## TABLE I

RESULTS OF LITERATURE SURVEY

| Data <br> System | Electrolytic Conductance | Diffusivity | Transport Number |

| $\mathrm{HNO}_{3}-\mathrm{NaHO}_{3}-\mathrm{H}_{2} \mathrm{O}$ | O ---- | 28 | ---- |

The experimental data were points taken at $0.1 \mathrm{eq} / 1$. increments from a smooth curve through the experimentally determined values of $D, k$, and $t^{+}$in the range of 0 to $1 \mathrm{eq} . / 1$. The $D_{p}, k_{p}$, and $t_{p}^{+}$ are complicated functions of the model parameters. It is these parameters which are adjusted to give a minimum in the sum of squares of the errors (as defined in Eq. (1)). Expressions such as $\left(1-D_{e} / D_{p}\right)$ are used rather than simply $\left(D_{p}-D_{e}\right)$, etc., so that each type of transport data has equal weight in determining the optimum coefficients. The goal is to obtain a single set of parameters which will give a good representation of all three types of data over the selected range of concentration.

## Optimization Procedure

Because Eq. (1) is a highly non-linear function of the system parameters, considerable difficulty was experienced in finding op timum model parameters. The procedure finally developed was essentially a steepest descent procedure with an acceleration step to speed convergence. Double precision programming was used upon nearing an optimum solution. The acceleration step was a "creep-and-leap" procedure in which a straight-forward steepest ascent was carried out for five iterations using a very small step length. Then the pattern of these small steps was projected using a step length such that if it were doubled, an over-shooting would result (i.e. a worse rather than a better result). In this way the length of the "leap" was nearly the largest permissible, and yet a better result was still guaranteed following the "leap".

Only the numerical procedures for parameter optimization have been outlined. Presumably, this procedure could be used successfully to obtain parameters for a number of models. Here, a particular model was developed and tested.

## Model Development

A model for multicomponent mass transport consists of a flux expression for each component in the system. The flux equations must be an explicit expression containing: driving forces, $\mathrm{F}_{\mathrm{i}}$, concentrations, and system parameters. From irreversible thermodynamics, the general form of these flux expressions is known to be linear in the forces. Thus, in a system of n-components, the flux of species $i, J_{i}$, must be of the form shown in Eq. (2):

$$
\begin{equation*}
\mathrm{J}_{\mathrm{i}}={\underset{j}{\mathrm{j}}}_{\mathrm{n}} \quad \mathrm{~L}_{\mathrm{ij}} \mathrm{~F}_{\mathrm{j}} \tag{2}
\end{equation*}
$$

The $L_{i j}$ are the phenomenological coefficients, and these are complex functions of concentration and system parameters, but are independent of the forces, $\mathrm{F}_{\mathrm{j}}$. A model for multicomponent mass transport gives an explicit, algebraic expression for the $\mathrm{L}_{\mathrm{ij}}$ in terms of the concentrations, $\mathrm{C}_{\mathrm{j}}$, and the system parameters. In the model developed for testing here, the system parameters are given the symbol $\mathrm{N}_{\mathrm{ij}}$.

While the same general model is used for mass transport in both membranes and aqueous solutions, there are differences. These differences arise because of an immobilized species present in the membrane--the membrane matrix. Because of this special feature, the basic set of flux equations governing mass transport in membranes form an independent set. While very similar flux expressions govern mass transport in aqueous solutions, the appropriate set of flux expressions is not independent. One of the significant advantages of the model developed here is that it is equally applicable to both the membrane and solution cases. However, in determining the range of convergence of the model developed here it is necessary to consider the membrane and solution cases separately.

Model for_Membranes
In the model developed here, there are postulated frictional forces between species i and j . These forces are taken proportional to the product of the concentration of species $\mathrm{j}, \mathrm{C}_{\mathrm{j}}$, and the relative velocity of species i with respect to species j . The total frictional force, $\mathrm{f}_{\mathrm{i}}$, is set equal to the negative of the total external force on species $\mathrm{i}, \mathrm{F}_{\mathrm{i}}$, taken to be the negative of the gradient of the total potential. These assumptions lead to a set of equations of the following form. Similar expressions have been obtained by others.

$$
\begin{equation*}
\mathrm{F}_{\mathrm{i}}=\sum_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}}\left(\mathrm{u}_{\mathrm{i}}-\mathrm{u}_{\mathrm{j}}\right) \quad \mathrm{j} \neq \mathrm{i} \tag{3}
\end{equation*}
$$

There are n-mobile components, and one fixed component, m , the membrane being treated as a completely homogeneous phase in which the matrix material is included as a component. Membrane swelling is allowed for by including a concentration term, $\mathrm{C}_{\mathrm{m}}$, for the matrix material.

If the set of linear equations of the form of (3) are solved for the species velocities $u_{i}$, the flux equations $J_{i}$ can be calculated as follows:

$$
\begin{equation*}
\mathrm{J}_{\mathrm{i}}=\mathrm{C}_{\mathrm{i}} \mathrm{u}_{\mathrm{i}} \tag{4}
\end{equation*}
$$

Solution of (3) for the $u_{i}$ is straightforward, but even for a single 1-1 electrolyte, the results are fairly complex, for solution (3) is rewritten so that each species velocity appears but once:

$$
\begin{equation*}
\mathrm{F}_{\mathrm{i}}=\mathrm{u}_{\mathrm{i}} \sum \mathrm{C}_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}}-\sum_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}} \mathrm{u}_{\mathrm{j}} \quad \mathrm{j} \neq \mathrm{i} \tag{5}
\end{equation*}
$$

For a system of $n+1$ components, the set of equations given by (5) can be written in matrix notations, a bracket indicating that the enclosed array is a matrix:

$$
\left[\begin{array}{c}
F_{1}  \tag{6}\\
F_{2} \\
\cdot \\
\cdot \\
F_{n}
\end{array}\right]=\left[\begin{array}{lllll}
A_{11} & A_{12} & \cdots & \cdots & A_{1 n} \\
A_{21} & A_{22} & \cdots & \cdots & A_{2 n} \\
\cdot & \cdots & \cdots & \cdots & \cdot \\
\cdot & \cdots & \cdots & \cdot & \cdot \\
A_{n l} & \cdots & \cdots & A_{n n}
\end{array}\right]\left[\begin{array}{c}
u_{1} \\
u_{2} \\
\cdot \\
\cdot \\
u_{n}
\end{array}\right]
$$

The $\mathrm{A}_{\mathrm{ij}}$ have been introduced for convenience and related to the $\mathrm{C}_{\mathrm{j}}$ and $\mathrm{N}_{\mathrm{ij}}$ as follows:

$$
\begin{align*}
& \mathrm{A}_{\mathrm{ii}}=\sum_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}} \quad \mathrm{j} \neq \mathrm{i}  \tag{7}\\
& \mathrm{~A}_{\mathrm{ij}}=-\mathrm{N}_{\mathrm{ij}} \mathrm{C}_{\mathrm{j}} \tag{8}
\end{align*}
$$

Equation (6) can be abbreviated if it is understood that $\mathrm{F}, \mathrm{A}$, and u represent the appropriate matrices:

$$
\begin{equation*}
[\mathrm{F}]=[\mathrm{A}][\mathrm{u}] \tag{9}
\end{equation*}
$$

The solution of (9) leads to a similar matrix equation where $A^{-1}$ is now the inverse matrix of A .

$$
\begin{equation*}
[\mathrm{u}]=\left[\mathrm{A}^{-1}\right][\mathrm{F}] \tag{10}
\end{equation*}
$$

Since matrix A is of order n and there are $\mathrm{n}+1$ components in the system, matrix A is non-singular in the model given here. Thus, the inverse matrix can be found by standard means. However, this holds only for the case where the matrix material is considered as a component so that there are a total of $n+1$ components in the the system.

The flux equations are found by multiplying the u's in (10) by the appropriate concentrations. In matrix notation this can be written as follows:

$$
\begin{equation*}
[\mathrm{J}]=[\mathrm{C}][\mathrm{I}]\left[\mathrm{A}^{-1}\right][\mathrm{F}] \tag{11}
\end{equation*}
$$

Results of the form shown by (11) are such that for a four component system there are four external forces and each is multiplied by a term involving a third order determinant divided by a fourth order determinant. It is thus evident that the algebra is rapidly becoming complicated. Nonetheless, if the $\mathrm{N}_{\mathrm{ij}}$ is known, direct matrix inversion would remain a reasonable procedure since wellknown numerical methods are available. However, the $\mathrm{N}_{\mathrm{ij}}$ must in general be determined from experiments involving the flux equations or quantities derivable from them. This is where difficulty is encountered. The purpose here is to show how the exact flux equations can be approximated to give expressions of greatly reduced complexity. In this way, the task of extracting the $\mathrm{N}_{\mathrm{ij}}$ 's from experimental data is greatly facilitated.

First, it will be noted that the diagonal terms in the matrix in (6) are the major elements. The off-diagonal terms would be expected to be significantly smaller than the diagonal terms. This
suggests a procedure for obtaining an approximate inverse. In particular, a first approximation is obtained by setting the off-diagonal terms equal to zero. The first approximate inverse to matrix $A$ is then $A_{1}{ }^{-1}$.

$$
\left[A_{1}^{-1}\right]=\left[\begin{array}{lllll}
1 / A_{11} & 0 & \cdot & \cdot & \cdot  \tag{12}\\
0 & 1 / A_{22} & . & . \\
. & & & \cdot & .
\end{array}\right]
$$

This approximate inverse corresponds to fluxes in a hypothetical case where each species moves through the membrane with the other species held fixed. With this first approximation, a more realistic inverse results from use of a second order iteration formula which is reported to converge rapidly. This is as follows:

$$
\begin{equation*}
\left[\mathrm{A}_{2}^{-1}\right]=\left[\mathrm{A}_{1}^{-1}\right]\left[21-\mathrm{AA}_{1}^{-1}\right] \tag{13}
\end{equation*}
$$

Here $\mathrm{A}_{1}{ }^{-1}$ is the first approximate inverse, $\mathrm{A}_{2}{ }^{-1}$ is a second approximation to the true inverse of $A$, and $I$ is a unit matrix. Applying this to (12), one obtains the following approximate inverse:

$$
\left[\mathrm{A}_{2}^{-1}\right]=\left[\begin{array}{llll}
1 / \mathrm{A}_{11} & -\mathrm{A}_{12} / \mathrm{A}_{11} \mathrm{~A}_{22} & -\mathrm{A}_{13} / \mathrm{A}_{11} \mathrm{~A}_{33} & \cdot  \tag{14}\\
-\mathrm{A}_{21} / \mathrm{A}_{22} \mathrm{~A}_{11} & 1 / \mathrm{A}_{22} & \cdot & \cdot \\
-\mathrm{A}_{31} / \mathrm{A}_{33} \mathrm{~A}_{11} & \cdot & 1 / \mathrm{A}_{33} & \cdot \\
-\mathrm{A}_{31} / \mathrm{A}_{33} \mathrm{~A}_{11} & \cdot & \cdot & \cdot
\end{array}\right]
$$

The iteration formula could be again applied to $\mathrm{A}_{2}{ }^{-1}$ but this would result in a significantly more complicated approximate inverse. No further refinement of the approximate inverse will be sought here.

The condition for convergence of (13) is that the off-diagonal terms in the matrix $A$ (given in (6)) be less than the diagonal terms. The diagonal terms are $\mathrm{A}_{\mathrm{i}}$, while the off-diagonal terms
are of the form $A_{i j}$. Thus, one needs to show that $A_{i j} / A_{j j}$ is less than one. Since the $A_{i i}$ terms are sums of the form $\underset{j \neq i}{N} C_{j} N_{i j}$, while the $A_{i j}$ are single terms of the form $C_{j} N_{i j}$, this condition will usually be satisfied, particularly since the large term $C_{m} N_{m}$ will always appear in the $\mathrm{A}_{\mathrm{ii}}$ term and never as an $\mathrm{A}_{\mathrm{ij}}$ term.

At this point, it is convenient to introduce generalized mobilities, $\mathrm{U}_{\mathrm{i}}$, which are defined by (15).

$$
\begin{equation*}
\mathrm{U}_{\mathrm{i}}=1 / \mathrm{A}_{\mathrm{ii}}=\underset{\mathrm{j}}{ }\left(\sum \mathrm{~N}_{\mathrm{ij}} \mathrm{C}_{\mathrm{j}}\right)^{-1} \quad \mathrm{j} \neq \mathrm{i} \tag{15}
\end{equation*}
$$

With this definition, the approximate flux expressions can be written in simple form:

$$
\begin{equation*}
\mathrm{J}_{\mathrm{i}}=\mathrm{U}_{\mathrm{i}} \mathrm{C}_{\mathrm{i}} \mathrm{~F}_{\mathrm{i}}+\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \Sigma \mathrm{~N}_{\mathrm{j}} \mathrm{~N}_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{~F}_{\mathrm{j}} \quad \mathrm{j} \neq \mathrm{i} \tag{16}
\end{equation*}
$$

Neglecting the explicit $\mathrm{N}_{\mathrm{ij}}$ in (16) a form results which is similar to the Nernst-Planck Equations, namely:

$$
\begin{equation*}
\mathrm{J}_{\mathrm{i}}=\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{~F}_{\mathrm{i}} \tag{17}
\end{equation*}
$$

By comparison with Eq. (2), one obtains the following predictive expressions for the $\mathrm{L}_{\mathrm{ij}}$. These predictive expressions for the $\mathrm{L}_{\mathrm{ij}}$ then constitute the model for mass transport in membranes:

$$
\begin{align*}
& \mathrm{L}_{\mathrm{ii}}=\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}}  \tag{18}\\
& \mathrm{~L}_{\mathrm{ij}}=\mathrm{N}_{\mathrm{ij}} \mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{C}_{\mathrm{j}} \mathrm{U}_{\mathrm{j}}  \tag{19}\\
& i \neq j \\
& j \neq i \tag{20}
\end{align*}
$$

From the predictive expressions for the $\mathrm{L}_{\mathrm{ij}}$, it is possible to predict the theoretical expressions for the transport coefficients $\mathrm{D}_{\mathrm{p}}, \mathrm{k}_{\mathrm{p}}$ and $\mathrm{t}_{\mathrm{p}}^{+}$(for the binary solutions) and this will be given after the model for mass transport in aqueous solutions is developed.

Interestingly enough, the solution model is identical to the result for the membrane, although the method of obtaining it is quite different and the conditions for convergence are different. It will, of course, be realized that the matrix iteration formula used to develop the membrane model can not be applied directly to the singular set of solution flux expressions, and hence a difference in approach is needed in the solution case.

Model for Aqueous Solutions
As in the membrane case, Eq. (2) is the starting point, but in the solution case there are simply N -mobile components. This set of flux expressions can also be written in the matrix form given by Eq. (9). There is the complication here that the coefficient matrix formed from the set of equations given by Eq. (3) is singular. Hence, before an exact matrix inversion can be carried out, certain operations must be carried out; ordinarily, the N -th flux is algebraically eliminated and the N -th force expression is dropped. But in doing this, a great deal of the simplicity of Eq. (3) is lost.

Because the approximation procedure to be used here involves only algebraic rearrangement of the singular set, the procedure can be used without first converting the singular set into a non-singular set. Thus, the approximate procedures used here have the property of transforming a singular set of force expressions into a singular set of flux expressions.

In the case considered here, each element in the matrix (to be inverted) is already a moderately complex function. The further complication introduced by the inversion yields functions of the concentrations and the parameters (i.e. the $\mathrm{N}_{\mathrm{ij}}$ ) that are so complex that the task of extracting the parameters from experimental data is impractical. In such a case, two possible alternatives are: (1) to assume the highly non-linear functions of concentrations to be sensibly constant over the range of concentrations of interest or (2) to approximate the inversion process so that simpler functions result. The latter approach has been used here. Approach (1) can be used providing one is simply interested in correlating a single type of experimental data over a small range of concentrations.

For reasons that will become apparent later, Eq. (3) is rewritten so that each species velocity appears but once:

$$
\begin{equation*}
\mathrm{F}_{\mathrm{i}}=\mathrm{u}_{\mathrm{i}} \sum_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}}-\sum_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}} \mathrm{u}_{\mathrm{j}} \quad \mathrm{j} \neq \mathrm{i} \tag{21}
\end{equation*}
$$

The first sum in Eq. (21) is defined to be a generalized mobility, $\mathrm{U}_{\mathrm{i}}$, and an ideal flux, $\mathrm{J}_{\mathrm{i}}^{*}$, is introduced and defined by Eq. (23).

$$
\begin{align*}
& \mathrm{U}_{\mathrm{i}}=1 / \sum_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}} \quad \mathrm{j} \neq \mathrm{i}  \tag{22}\\
& \mathrm{~J}_{\mathrm{i}}^{*}=\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{~F}_{\mathrm{i}} \tag{23}
\end{align*}
$$

With these definitions, Eq. (21) can be recast as follows:

$$
\begin{equation*}
\mathrm{J}_{\mathrm{i}}=\mathrm{J}_{\mathrm{i}}^{*}+\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \sum_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}} \mathrm{~J}_{\mathrm{i}} \quad \mathrm{j} \neq \mathrm{i} \tag{24}
\end{equation*}
$$

Equation (24) is simply Eq. (21) with the definitions in Eqs. (22) and (23) introduced. No approximations have been made, and only the form of Eq. (21) has been changed.

Why the $\mathrm{J}_{\mathrm{i}}^{*}$ are called ideal fluxes and why the $\mathrm{U}_{\mathrm{i}}$ are termed generalized mobilities can be seen from Eq. (24). Suppose that all of the fluxes were zero except for a particular one, $\mathrm{J}_{\mathrm{i}}$. Then $\mathrm{J}_{\mathrm{i}}$ would be equal to $\mathrm{J}_{\mathrm{i}}^{*}$. Thus, $\mathrm{J}_{\mathrm{i}}$ would be directly proportional to $\mathrm{F}_{\mathrm{i}}$. The proportionality constant would be equal to the product of the generalized mobility and the concentration of species i. This will, of course, be recognized as being in the form of the so-called "Nernst-Planck" flux equations.

From the foregoing discussion, one apparent method of approximating the inversion of Eq. (21) is to neglect the second term on the right hand side of Eq. (24). Then using Eq. (23), a NernstPlanck expression is obtained in which the generalized mobilities, $\mathrm{U}_{\mathrm{i}}$, have a particular concentration dependence. Hence, as a first order approximation, one obtains the following inverted form:

$$
\begin{equation*}
\mathrm{J}_{\mathrm{i}}=\mathrm{J}_{\mathrm{i}}^{*}=\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{~F}_{\mathrm{i}} \tag{25}
\end{equation*}
$$

where:

$$
\mathrm{U}_{\mathrm{i}}=1 / \sum_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}} \quad \mathrm{j} \neq \mathrm{i}
$$

Higher order approximations can be obtained in the following way: starting with the form of Eq. (24) one writes a general expression for the flux of a species j and introduces another index k .

$$
\begin{equation*}
\mathrm{J}_{\mathrm{j}}=\mathrm{J}_{\mathrm{j}}^{*}+\mathrm{C}_{\mathrm{j}} \mathrm{U}_{\mathrm{j}} \sum_{\mathrm{k}} \mathrm{~N}_{\mathrm{jk}} \mathrm{~J}_{\mathrm{k}} \quad \mathrm{k} \neq \mathrm{j} \tag{26}
\end{equation*}
$$

This expresssion for $\mathrm{N}_{\mathrm{j}}$ is then substituted into Eq. (24) to give:

$$
\begin{equation*}
\mathrm{J}_{\mathrm{i}}=\mathrm{J}_{\mathrm{i}}^{*}+\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \sum_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}} J_{\mathrm{j}}^{*}+\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \sum_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}} \mathrm{C}_{\mathrm{j}} \mathrm{U}_{\mathrm{j}} \sum_{\mathrm{k}} \mathrm{~N}_{\mathrm{jk}} \mathrm{~J}_{\mathrm{k}} \mathrm{j} \neq \mathrm{i}, \mathrm{k} \neq \mathrm{j} \tag{27}
\end{equation*}
$$

This process of substituting Eq. (24) into itself yields a new expression with three terms on the right hand side; the first containing no explicit $N_{i j}$ 's, a second term which is linear in the $\mathrm{N}_{\mathrm{ij}}$ 's, and a third term which is quadratic in the $\mathrm{N}_{\mathrm{ij}}$ 's. This substitution process can be continued by eliminating $\mathrm{J}_{\mathrm{k}}$ from Eq. (27) to give a term which is third order in the $\mathrm{N}_{\mathrm{ij}}$ 's. Further substitution gives a term which is fourth order in the $\mathrm{N}_{\mathrm{ij}}$ 's, etc. At each stage, only the last term contains $\mathrm{J}_{\mathrm{j}}$ 's; the other terms contain only $\mathrm{J}_{j}^{*}$ 's. The general approximation scheme, then, is to expand Eq. (24) by substituting it into itself until the terminal factor becomes negligible. With neglect of the last term in Eq. (27), for example, one obtains the following form:

With Eq. (23) this is cast in the desired, inverted from as follows:

$$
\begin{equation*}
\mathrm{J}_{\mathrm{i}}=\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{~F}_{\mathrm{i}}+\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \sum \mathrm{~N}_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{U}_{\mathrm{j}} \mathrm{~F}_{\mathrm{j}} \quad \mathrm{j} \neq \mathrm{i} \tag{29}
\end{equation*}
$$

This is exactly the result obtained for the membrane case, Eq. (16). Thus, the predictive expressions for the $\mathrm{L}_{\mathrm{ij}}$ are also given by Eqs. (18) and (19).

It remains to be shown that each succeeding term in a form such as Eq. (27) is smaller than its predecessor, since this is not evident upon casual inspection. One method of demonstrating this is to suppose that all of the $\mathrm{N}_{\mathrm{ij}}$ 's are identical. This might be the case, for example, if one had several isotopes of the same parent compound.

With the velocities in Eq. (21) with respect to the molar average, the fluxes sum to zero:

$$
\sum_{\mathrm{j}=1}^{\mathrm{n}} \mathrm{~J}_{\mathrm{j}}=0
$$

Combining Eqs. (29) and (30), one obtains:

$$
\begin{equation*}
\mathrm{J}_{\mathrm{i}}=\mathrm{J}_{\mathrm{i}}^{*}+\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{~N}_{\mathrm{ij}}\left(-\mathrm{J}_{\mathrm{i}}\right) \tag{31}
\end{equation*}
$$

Solving for the ratio of $\mathrm{J}_{\mathrm{i}}^{*}$ to $\mathrm{J}_{\mathrm{i}}$ and introducing a new symbol $a_{\mathrm{i}}$, results in the following:

$$
\begin{equation*}
\mathrm{J}_{\mathrm{i}}^{*} / \mathrm{J}_{\mathrm{i}}=1+\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{~N}_{\mathrm{ij}}=1+a_{\mathrm{i}} \tag{32}
\end{equation*}
$$

The symbol $a_{\mathrm{i}}$ has been introduced and one should remember that the term $\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{N}_{\mathrm{ij}}$ will be equal to $a_{\mathrm{i}}$ only for the special case of equal $\mathrm{N}_{\mathrm{ij}}$ 's. Rearranging Eq. (32) and expanding in an appropriate series form, one obtains:

$$
\mathrm{J}_{\mathrm{i}}=\begin{array}{ll}
\mathrm{J}_{\mathrm{i}}^{*}\left(1-a_{\mathrm{i}}+a_{\mathrm{i}}^{2}-\ldots-\right)^{2} & \text { If } a_{\mathrm{i}} \leq 1 \\
\mathrm{~J}_{\mathrm{i}}^{*}\left(1 / a_{\mathrm{k}}-1 / a_{\mathrm{k}}^{2}+1 / a_{\mathrm{k}}^{3} \ldots--\right) \text { If } a_{\mathrm{k}} \geq 1 \tag{33}
\end{array}
$$

From substitution of the definition of $\mathrm{U}_{\mathrm{i}}$ into Eq. (32), it is seen that the $a_{\mathrm{i}}$ are simply related to the concentrations expressed as mole fractions, $\mathrm{X}_{\mathrm{i}}$ :

$$
\begin{equation*}
a_{\mathrm{i}}=\mathrm{X}_{\mathrm{i}} /\left(1-\mathrm{X}_{\mathrm{i}}\right) \tag{34}
\end{equation*}
$$

However, this simple result applies only for the special case of equal $\mathrm{N}_{\mathrm{ij}}$. Also, only one $a$, denoted as $a_{\mathrm{k}}$, can be greater than unity (i.e. $\mathrm{X}_{\mathrm{k}}>0.5$ ). In the general multicomponent case, there need be no a greater than unity. Frequently, however, the solvent species mole fraction will be nearly unity, in which case the $a$ for the solvent species will be quite large.

Substitution of Eq. (32) into Eq. (29) gives:

$$
\begin{equation*}
\left.\mathrm{J}_{\mathrm{i}}=\mathrm{J}_{\mathrm{i}}^{*}+a_{\mathrm{i}}\left[\sum_{\mathrm{j}}^{\left[\mathrm{I}-a_{\mathrm{j}}\right.}+a_{\mathrm{j}}^{2} \ldots\right) \mathrm{J}_{\mathrm{j}}^{*}+\left(\mathrm{l} / a_{\mathrm{k}}-1 / a_{\mathrm{k}}^{2} . .\right) \mathrm{J}_{\mathrm{k}}^{*}\right] \tag{35}
\end{equation*}
$$

$=\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{F}_{\mathrm{i}}+a_{\mathrm{i}}\left[\sum_{\mathrm{j}}\left(1-a_{\mathrm{j}}+a_{\mathrm{j}}^{2} \ldots\right) \mathrm{U}_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{F}_{\mathrm{j}}+\left(\mathrm{l} / a_{\mathrm{k}}-\mathrm{l} / a_{\mathrm{k}}{ }^{2}+\mathrm{l} / a_{\mathrm{k}}{ }^{3}\right)\right.$

$$
\begin{equation*}
\left.\mathrm{U}_{\mathrm{k}} \mathrm{C}_{\mathrm{k}} \mathrm{~F}_{\mathrm{k}}\right] \tag{35}
\end{equation*}
$$

where: $\mathrm{j} \neq \mathrm{i}, \mathrm{k} \quad a \mathrm{j} \leq 1$

$$
\mathrm{k} \neq \mathrm{i}, \mathrm{j} \quad a_{\mathrm{k}} \geq 1
$$

Equation (35) gives a result that can be compared with the successive approximation scheme for the special case of equal $\mathrm{N}_{\mathrm{ij}}$. In this form, the requirements for rapid convergence can be seen, namely, the $a_{\mathrm{j}}$ should be small, and the $a_{\mathrm{k}}$, if any, should be large.

For example, by neglecting terms of order $a_{i} a_{j}$ and higher, and terms of order $a_{\mathrm{i}} / a_{\mathrm{k}}$ and higher, one obtains the following approximate expression:

$$
\begin{align*}
\mathrm{J}_{\mathrm{i}} & =\mathrm{J}_{\mathrm{i}}^{*}+a_{\mathrm{i}} \sum_{\mathrm{j}} \mathrm{~J}_{\mathrm{i}}^{*}  \tag{36}\\
& =\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{~F}_{\mathrm{i}}+a_{\mathrm{i}} \sum_{\mathrm{j}} \mathrm{C}_{\mathrm{j}} \mathrm{U}_{\mathrm{j}} \mathrm{~F}_{\mathrm{j}}
\end{align*}
$$

This same expression results from neglecting the last term in Eq. (27).

For very small concentrations of solute, the corresponding $a_{i}$ becomes very small, and $\mathrm{J}_{\mathrm{i}}$ might be taken as $\mathrm{J}_{\mathrm{i}}^{*}$ for the solutes.

However, note that using a similar expression for the solvent would be quite invalid since $a_{\mathrm{k}}$ would be very large, and thus Eq. (36) could not be further simplified.

The general form in which the $\mathrm{N}_{\mathrm{ij}}$ 's are not necessarily equal, and where no particular reference is specified, can be written as follows:

$$
\begin{align*}
& \mathrm{J}_{\mathrm{i}}=\mathrm{J}_{\mathrm{i}}^{*}+\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} {\left[\sum_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}}\left(1-a_{\mathrm{j}}+a_{\mathrm{j}}^{2}-a_{\mathrm{j}}^{3}-\cdots\right) \mathrm{N}_{\mathrm{j}}^{*}\right.} \\
&\left.+\mathrm{N}_{\mathrm{ik}}\left(\mathrm{l} / a_{\mathrm{k}}-1 / a_{\mathrm{k}}^{2} \cdots\right) \mathrm{N}_{\mathrm{k}}^{*}\right] \\
&=\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{~F}_{\mathrm{i}}+\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}}\left[\sum_{\mathrm{j}} \mathrm{~N}_{\mathrm{ij}}\left(1-a_{\mathrm{j}}+a_{\mathrm{j}}^{2} \cdots\right) \mathrm{C}_{\mathrm{j}} \mathrm{U}_{\mathrm{j}} \mathrm{~F}_{\mathrm{j}}\right. \\
&\left.+\mathrm{N}_{\mathrm{ik}}\left(\mathrm{l} / a_{\mathrm{k}}-1 / a_{\mathrm{k}}^{2} \cdots\right) \mathrm{N}_{\mathrm{k}}\right]  \tag{37}\\
& \mathrm{j} \neq \mathrm{i}, \mathrm{k}
\end{align*}
$$

Again, clearly, the method will converge if the $a_{i}$ 's and $a_{j}$ 's are small, and the $a_{\mathrm{k}}$ large. However, the simple interpretation that the $a_{\mathrm{j}}$ 's are equal to $\mathrm{C}_{\mathrm{i}} \mathrm{U}_{\mathrm{i}} \mathrm{N}_{\mathrm{ij}}$ is no longer valid.

Predictive Expressions
From the basic model, given by Eqs. (18) through (20), the expressions can be derived for the transport coefficients of interest in binary aqueous solutions, that is: the diffusion coefficient $D_{p}$, the electrical conductivity $\mathrm{k}_{\mathrm{p}}$, and the cation transport number $\mathrm{t}_{\mathrm{p}}{ }^{+}$. The model in this case can be used to predict the concentration dependence of these transport coefficients in terms of concentrations and model parameters. These derivations will not be given here since the detail can be found elsewhere. Here, only the resulting predicted expressions for the transport coefficients will be given. These are as follows:

$$
\begin{equation*}
\mathrm{D}_{\mathrm{p}}=(2 \mathrm{RT} / \mathrm{F})\left(\mathrm{U}_{1} \mathrm{U}_{2}-\mathrm{C}^{2} \mathrm{~N}_{12}{ }^{2} \mathrm{U}_{1}{ }^{2} \mathrm{U}_{2}^{2}\right) /\left(\mathrm{U}_{1}+\mathrm{U}_{2}-2 \mathrm{CN}_{12} \mathrm{U}_{1} \mathrm{U}_{2}\right) \tag{38}
\end{equation*}
$$

$$
\begin{align*}
& \mathrm{k}_{\mathrm{p}}=\mathrm{C}\left(\mathrm{U}_{1}+\mathrm{U}_{2}-2 \mathrm{CN}_{12} \mathrm{U}_{1} \mathrm{U}_{2}\right)  \tag{39}\\
& \mathrm{t}_{\mathrm{p}}^{+}=\left(\mathrm{U}_{1}-\mathrm{CN}_{12} \mathrm{U}_{1} \mathrm{U}_{2}\right) /(\mathrm{k} / \mathrm{C}) \tag{40}
\end{align*}
$$

where: $\mathrm{R}=$ gas const.
F = Faraday

The parameter $\mathrm{U}_{\mathrm{i}}$ is introduced for convenience and is termed a generalized mobility. It is easily expressed in terms of $\mathrm{C}_{\mathrm{i}}$ 's and $\mathrm{N}_{\mathrm{ij}}$ 's (see Eq. (20)), but its use allows simplifications in writing mathematical expressions This mobility also has the physical significance of a true mobility.

For ternary and more complex mixtures, only electrical conductivity data have been obtained. The expression for conductives of these 1-1 electrolyte mixtures is as follows:

$$
\begin{equation*}
\underset{\mathrm{p}}{\mathrm{k}_{\mathrm{p}}=\mathrm{RT} / \mathrm{F}\left(\Sigma \mathrm{~L}_{\mathrm{ij}}-\Sigma \mathrm{L}_{\text {ions }}\right)} \tag{41}
\end{equation*}
$$

Results

## Experimental Data

Because of the scanty data available for ternary systems, a complete set of electrical conductivity data for the system NaCl -$\mathrm{HNO}_{3}-\mathrm{H}_{2} \mathrm{O}$ was determined for the concentration range of $0-1 . \mathrm{ON}$. The determinations were made with a null bridge using a 60 cycle A. C. oscillator. All determinations were made at $25^{\circ} \mathrm{C}$. These data are shown as points in Figure (1). Correlations of these data are shown as curves and these theoretical results will be discussed presently.

Results of Numerical Analysis
Results for Binary Systems:
The literature data and the predicted data for the binary

FIG. (1) SPECIFIC CONDUCTANCE FOR $\mathrm{NaCl}-\mathrm{HCl}-\mathrm{H}_{2} \mathrm{O}$ SYSTEM AT $25^{\circ} \mathrm{C}$

systems $\mathrm{NaCl}-\mathrm{H}_{2} \mathrm{O}, \mathrm{HNO}_{3}-\mathrm{H}_{2} \mathrm{O}$, and $\mathrm{HCl}-\mathrm{H}_{2} \mathrm{O}$ are shown in Figures (2), (3), and (4). In all cases, the effective water of hydration of the solute has been taken to be 3.5 moles of $\mathrm{H}_{2} \mathrm{O} /$ mole of solute. Complete data for the system $\mathrm{NaNO}_{3}-\mathrm{H}_{2} \mathrm{O}$ was not available. Hence, this system has not been analyzed as yet.

## Effect of Water of Hydration:

Figure (5) shows the effect of water of hydration on the deviations between prediction and experiment. The sum of squares of the errors, defined in Eq. (1), is shown as a function of the number of hydrate for each mole of solute.

Tables (2), (3), and (4) show the predicted data and the associated optimum parameters for several assumed values for water of hydration.

Results for Ternary Systems:
The experimental and predicted electrical conductivities for the ternary system $\mathrm{NaCl}-\mathrm{HNO}_{3}-\mathrm{H}_{2} \mathrm{O}$ are shown in Figure (1). The data points are shown and the curves are predicted from the model for multicomponent mass transport. As with the binary systems, an optimum set of system parameters, the $\mathrm{N}_{\mathrm{ij}}$ 's, were found by the numerical search technique developed for use in model testing. However, it was necessary to determine only three of the ten parameters involved since values for the other seven were available from analysis of the binary data. Had complete data been available for the remaining possible binary system $\left(\mathrm{NaNO}_{3}-\mathrm{H}_{2} \mathrm{O}\right)$, only two parameters would have remained undetermined. The ten parameters, including the three that were determined from the ternary data, are given in Table (5). The first three parameters in the table are those determined from the ternary data.

TABLE IV
Optimum Parameters and Calculated Data for $\mathrm{HCl}-\mathrm{H}_{2} \mathrm{O}$ System for Various Waters of Hydration

## Discussion of Results

For the system $\mathrm{HCl}-\mathrm{H}_{2} \mathrm{O}$ and $\mathrm{NaCl}-\mathrm{H}_{2} \mathrm{O}$, the plots of the sum of squares of errors versus water of hydration show a definite minimum at a reasonable value of this parameter: about 5 moles $\mathrm{H}_{2} \mathrm{O} /$ mole HCl and about 1 mole $\mathrm{H}_{2} \mathrm{O} /$ mole NaCl . For the $\mathrm{HNO}_{3}-\mathrm{H}_{2} \mathrm{O}$ system, no minimum was found. A value of zero for this parameter gave the best fit of the data, negative values of this parameter being considered inadmissible on physical grounds. Another anomaly in the $\mathrm{HNO}_{3}-\mathrm{H}_{2} \mathrm{O}$ data is that (see Figure (4)) the theoretical fit of the transport data for this system appears inconsistent with the other results. It is quite possible that this data is in error and this may account for an unrealistic value indicated for the water of hydration in this system. It also appears that the $\mathrm{NaCl}-\mathrm{H}_{2} \mathrm{O}$ result is low, but almost equally good results were obtained at a more realistic value of this parameter (see Table (2)).

As can be seen from Tables (2), (3), and (4), the effective water of hydration has only a small effect on the fit between the experimental and predicted data so long as a value not too far removed from the optimum is chosen. Furthermore, when the same parameter $\left(\mathrm{N}_{\mathrm{ij}}\right)$ is compared for two binary systems (say the $\mathrm{N}_{\mathrm{ij}}$ coefficient for the $\mathrm{Cl}^{--}$and $\mathrm{H}_{2} \mathrm{O}$ interaction), the value should be the same for the model. This was approximately true for the $\mathrm{N}_{\mathrm{ij}}$ when the optimum waters of hydration were used, but an even closer agreement was achieved when the same value of the water of hydration was used for all of the systems.

Finally, there is the main point of how well the derived model fits the experimental data. It is quite easy to calculate an average percentage deviation from the sum of squares of the errors reported in Tables (2), (3), and (4). The figure shows the sum of squares of the percentage error for 33 points. The square root of this quantity divided by 33 is then approximately the average deviation between theory and experiment. Thus, for the system $\mathrm{NaCl}-$ $\mathrm{H}_{2} \mathrm{O}$ at a water of hydration of 3.5 , the sum of the squares of the errors is 0.03658 . The square root of this quantity divided by 33
gives an average fractional deviation of about .033 or 3.3 percent. For the system $\mathrm{HCl}-\mathrm{H}_{2} \mathrm{O}$ at water of hydration of 5.0 , a corresponding calculation gives an average deviation of about 2.1 percent. Thus, it can be seen that, typically, the model fits the data with an average deviation of 2 to 3 percent, and that all three types of data are about equally represented.

The largest deviations are in the concentration range . $0-0.1$ eq./l., a region in which the experimental transport coefficients undergo an anomalously large change also. This implies that the $\mathrm{N}_{\mathrm{ij}}$ 's, assumed constant in the model, are moderately concentration dependent in the region of low concentrations, and that perhaps the data should be divided into a low concentration group (i.e. 0 to $0.1 \mathrm{eq} . / 1$ ) and into a moderate to high concentration group (i.e. 0.1 to 1.0 eq./l.). This would undoubtedly lead to a very close agreement between theory and experiment, but would have the disadvantage of producing two sets of $\mathrm{N}_{\mathrm{ij}}$ rather than one. In any event, the comparison between theory and experiment for binary systems is well within the accuracy needed for engineering work, and the model can be used with confidence in this context.

The comparison of the theory with the ternary data is less satisfactory. At very low NaCl but at high $\mathrm{HNO}_{3}$ concentratıons, the deviations are as large as 25 percent. At moderate or low $\mathrm{HNO}_{3}$ concentrations, the agreement is fairly good throughout the range of NaCl concentrations and high NaCl and high $\mathrm{HNO}_{3}$ concentrations, the agreement is satisfactory. It is thought that some of the data is perhaps in error, and it is planned to recheck these experimental results before proceeding with further analysis.

Summary and Conclusions
A general model for multicomponent mass transport was developed. A numerical procedure was developed for determining the optimum parameters for mass transport models, and this was used to establish the optimum parameters for several systems for the particular model derived here. The mass transport model developed was shown to reproduce experimental transport data of several types over an extended range of concentrations with an average accuracy of about 2-3 percent.

Water of hydration was shown to be an important parameter in the determination of the average deviation between experimental and predicted data. In two cases studied ( $\mathrm{NaCl}, \mathrm{HCl}$ ), an optimum water of hydration was found, corresponding to a physically reasonable value for this parameter. In a third case $\left(\mathrm{HNO}_{3}\right)$ the optimum parameter was found to be zero, but there appear to be other anomalies in this same data.

Experimental electrical conductivities were measured in the system $\mathrm{NaCl}-\mathrm{HNO}_{3}-\mathrm{H}_{2} \mathrm{O}$, and optimum model parameters were extracted from this data. The comparison between experimental and theoretical results was less satisfactory for this ternary system than for the binary system in certain ranges of concentration and this was thought due to experimental errors.
