**EFFECTIVE AND TOTAL STRESS  
STRENGTH INTERPRETATION FOR SILTS**

by:

Bonifacio I. dela Pena

Thesis submitted to the Faculty of  
Virginia Polytechnic Institute and State University  
in partial fulfillment of the requirements for the degree  
of  
Master of Science  
In  
Civil Engineering

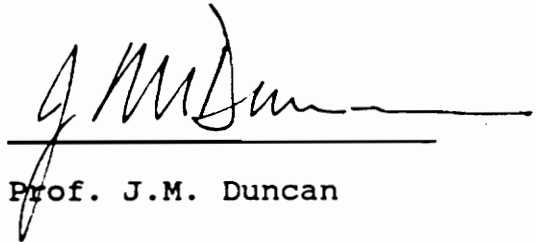

Approved:

Prof. T.L. Brandon, Chairman

Prof. G.W. Clough

Prof. J.M. Duncan

ABSTRACT

## ACKNOWLEDGEMENTS

The author wishes to express his sincere appreciation to his academic advisor and committee chairman, Professor Thomas L. Brandon, for his guidance, suggestions, encouragement, and support throughout the preparation of this report. The privilege and honor of working with Professor Brandon has enhanced the author's professional life and this is truly appreciated.

Appreciation is also extended to the other members of the author's committee, Professor G.W. Clough and Professor J.M. Duncan, for their support, encouragement, and patience.

The author also extends his appreciation to Professor Alice Kinder for the assistance she rendered in writing this report.

And finally, the author expresses his gratitude to his wife, Karina G. dela Pena, and daughter, Camille Angela G. dela Pena, for their love and support during the preparation of this thesis.

## CHAPTER 1

### INTRODUCTION

The purpose of this study is to investigate the primary factors which control the engineering behavior of silts. Although extensive expertise exists in dealing with the engineering behavior of sands and clays, relatively little experience exists in assessing the behavior of silts.

Silts may be classified in several ways. The ASTM classification states that silts are soils with grain sizes that ranges from 0.002 mm to 0.074 mm. According to the Unified Soil Classification System, silts are fine-grained soils with plasticity characteristics that plot below the A-line using Casagrande's plasticity chart. Terzaghi and Peck (1967) suggested that if silts are plastic, they can be treated like clays, and if non-plastic, they can be treated like sands.

These classifications currently used do not provide much basis to infer how silts will behave in the field for design purposes. Furthermore, basing the behavior of silts to either sands or clays does not help in assessing the engineering behavior.

One reason offered to explain why silts are among the least studied soil deposits concerns the unfavorable

effects of disturbance during sampling. Nacci et al. (1976) proposed using remolded samples of Rhode Island silt because tube and block sampling produced inferior results. The samples densified during transit to the laboratory. The decrease in void ratio due to the densification gives the undisturbed specimens higher strengths than that present in situ. Schultze et al. (1965) also tested reconstituted samples because of the same problem encountered in using undisturbed samples. Others have employed in-situ testing techniques to determine the shear strength of silt, but have encountered difficulties. Field vane shear tests were used by Ladd et al. (1985), but produced relatively high strengths attributed to partial drainage during shear. Kondrad et al. (1984) utilized the standard penetration test to estimate silt properties, and concluded that the results were not reliable because correlations for silts are not available.

Sands and clays differ from silts because they have methods of sampling or remolding that are well accepted for classification and determination of strength parameters. Undisturbed samples of clays can be readily obtained by thin walled sampling and block sampling. The effective stress induced by the negative pore pressure in the sample provides enough strength for samples to be

trimmed and tested in a triaxial apparatus. In-situ testing, such as the cone penetration test, proves to be useful because existing correlations are available to determine the field strength parameters. Correlations of index test results to field behavior also exist for clay. The undrained shear strength for normally consolidated clays can be evaluated by Skempton's correlation to undrained strength ratio, expressed as:

$$S_u/p = 0.11 + 0.0037(PI), \quad (1)$$

where PI is the plasticity index of the soil.

For sands, it is well accepted that thin walled samples or block samples are not possible to obtain in the field. Sands are very susceptible to vibrations, thus densification occurs due to handling of sand samples. The negative pore pressure present in the samples upon extrusion may not be sufficient for the samples to be trimmed for triaxial testing. For these reasons, reconstituted samples are used to determine the strength parameters of sands. In-situ tests, such as standard penetration tests and cone penetration tests, have proven to be useful in obtaining reliable estimates of friction angles and densities.

Due to the difficulties in assessing the engineering behavior of silts using convention correlations used for sands and clays, a literature review was undertaken to compare the documented behavior of silts to those of sands and clays.

In the course of this research study, series of UU and CU triaxial test results of different silt samples were gathered to investigate the factors that control the strength parameters of silts. Undrained strength parameters measured both from CU and UU triaxial tests are compared.

Silt samples which exhibit dilative behavior during undrained shear make it difficult to define failure. Because of this behavior, the test results were interpreted using different failure criteria to assess the effective stress friction angle and the undrained shear strength of the samples.

## CHAPTER 2

### PROBLEMS WITH TRIAXIAL TESTING ON SILTS

Brandon et al. (1990) pointed out several problems in determining the shear strength properties of silts using conventional triaxial testing. The problems cited are:

1. UU triaxial tests provide erratic results.
2. The dilative tendencies of low-plasticity silts make it difficult to define failure in undrained triaxial tests.
3. Loss of saturation may occur when triaxial specimens of silts are sheared in CU tests.

Conventional UU triaxial tests are useful in determining the undrained shear strength of cohesive soils, but some problems are encountered for using them with silts.

Golder and Skempton (1948) conducted a series of UU triaxial tests on saturated silts and clays. All saturated clay samples behaved as  $\phi_u=0$  materials, but for the silt samples, the angle of shearing resistance varied between  $18^\circ$  and  $38^\circ$ . The reason given by the authors was that dilatancy could have caused this type of behavior

for silts, but no further explanation was offered. Bishop and Edlin (1950) cited that the deviation from the  $\phi_u=0$  results were due to primarily to the departure from the constant-volume condition normally assumed in undrained tests on fully saturated samples. They stated that the departure from the constant-volume condition may be caused by:

1. Compressibility of water
2. Incomplete saturation or entrapped air
3. Negative pressure set up in the pore water

during shear of sufficient magnitude to cause cavitation.

Penman (1953) stated that if an undrained test is conducted on highly dilatent materials, cavitation occurs when pore pressures fall to about -14.7 psi.

Bishop and Edlin (1950) stated that  $\phi_u=0$  behavior should exist in UU triaxial test on saturated specimens having the same void ratio as long as the pore pressure is greater than the vapor pressure of water, which is equal to -14.7 psi. In cases where pore pressures decreases to -14.7 psi, the sample is no longer saturated and the sample behaves as  $\phi_u > 0$  material. The  $\phi$  measured from the UU triaxial tests would then be approximately equal to the effective stress friction angle of the sample when cavitation occurs.

If it is assumed that cavitation occurs at -14.7 psi, the maximum value of  $S_u$  which can be measured in UU tests can be calculated as a function of  $\phi'$ . Brandon et al. (1990) determined the contours of the maximum undrained shear strength,  $S_u$ , for the different values of effective stress friction angle  $\phi'$ . These are shown in Figure 1. If UU triaxial tests are conducted on saturated soil samples, the value of the undrained shear strength, which corresponds to a certain cell pressure, can be measured. If the relationship of the undrained shear strength,  $S_u$ , and cell pressure plots on the line corresponding to the effective friction angle measured for the samples, then it may be assumed that the samples cavitared. Figure 2 shows this condition by using the data measured by Golder and Skempton (1948) from UU tests on Estuary silts. It is believed that cavitation occurred because the data plot close to the  $\phi' = 24^\circ$  line, which is the same undrained friction angle measured for the test.

The deviator stress-strain relationship for silts may be somewhat different as compared to other types of soil. Shown in Figure 3 is the deviator stress-strain relationship measured using the CU triaxial test results for Cape Canaveral silt performed by Newhouse (1990). The deviator stress showed a rapid increase at small range of

Figure 1 Maximum Undrained Shear Strength Measured In UU Triaxial Test If Cavitation Occurs (Brandon et al., 1990)

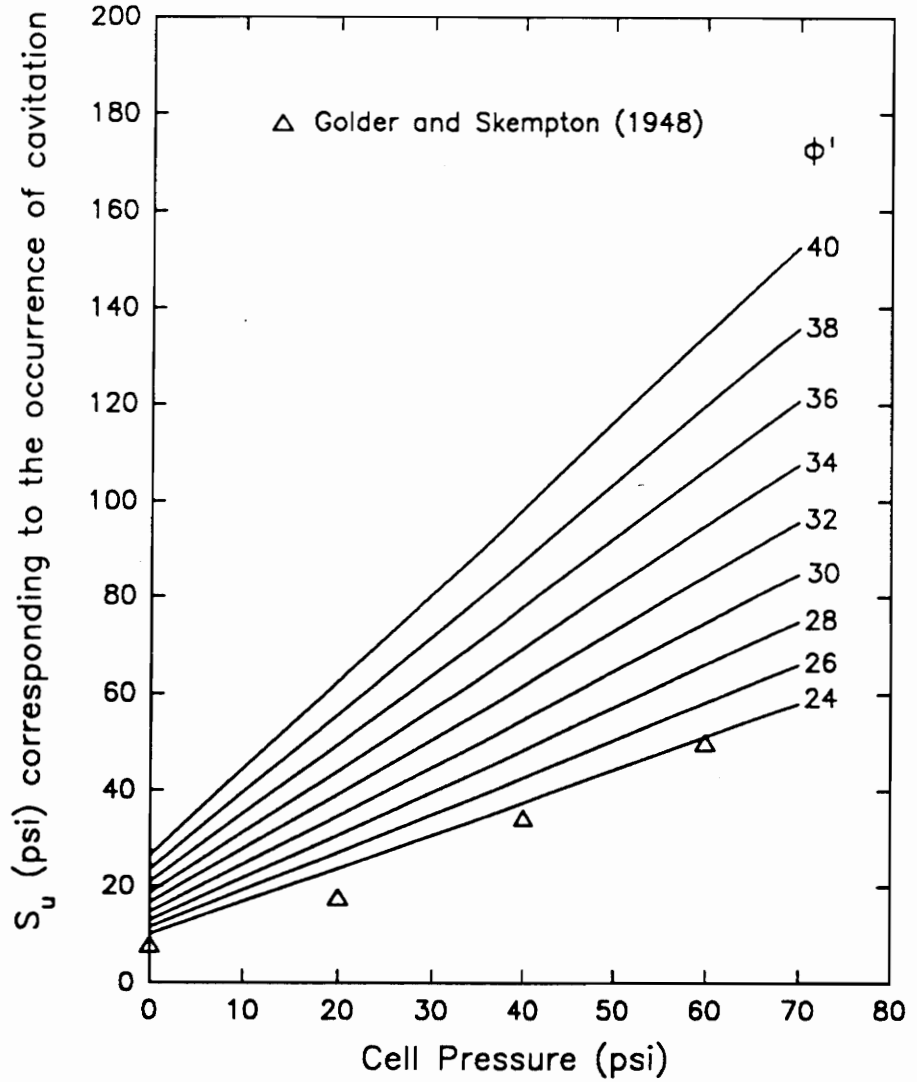

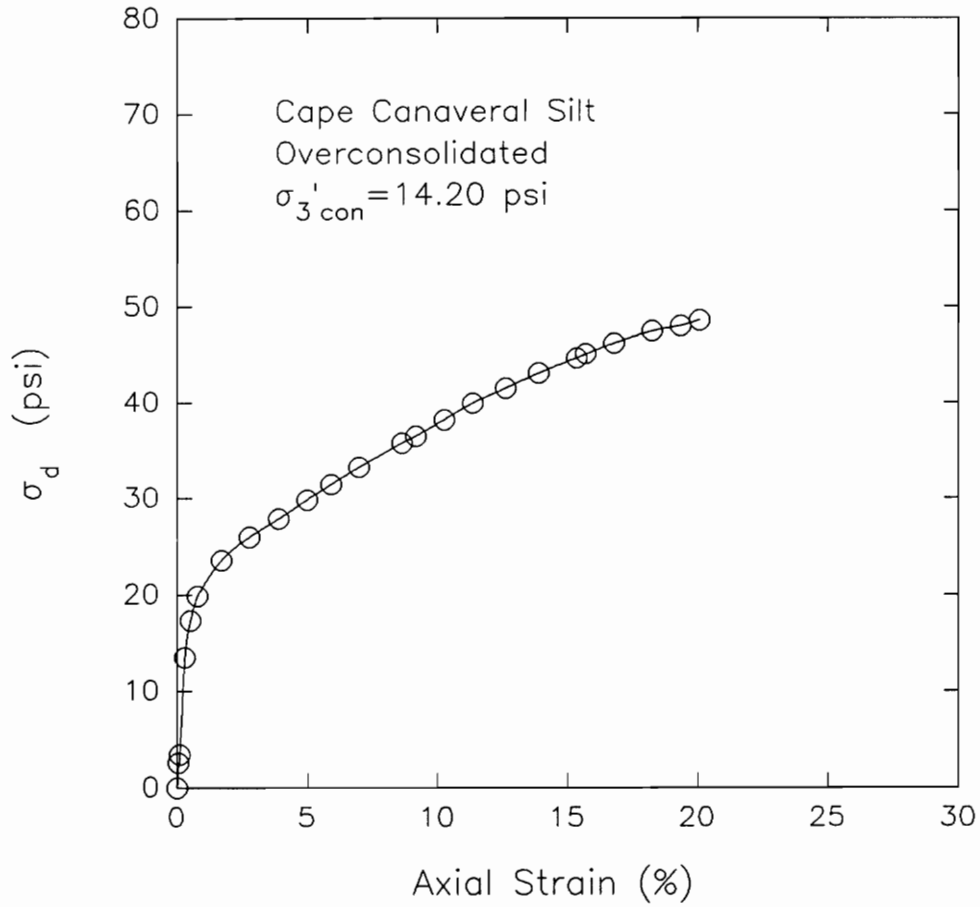

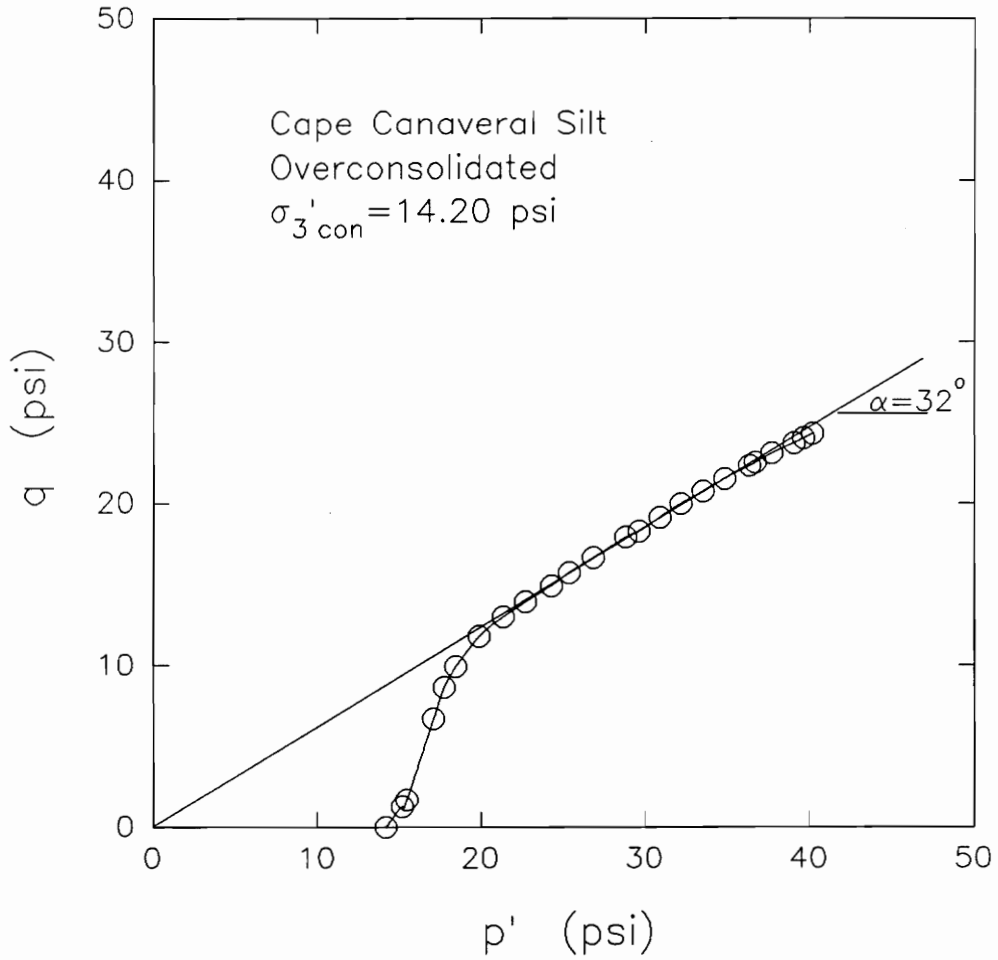

Figure 2 Golder and Skempton's (1948) Data For UU Triaxial Test On Clyde Estuary Silt Presented On Cavitation Plot (Brandon et al., 1990)

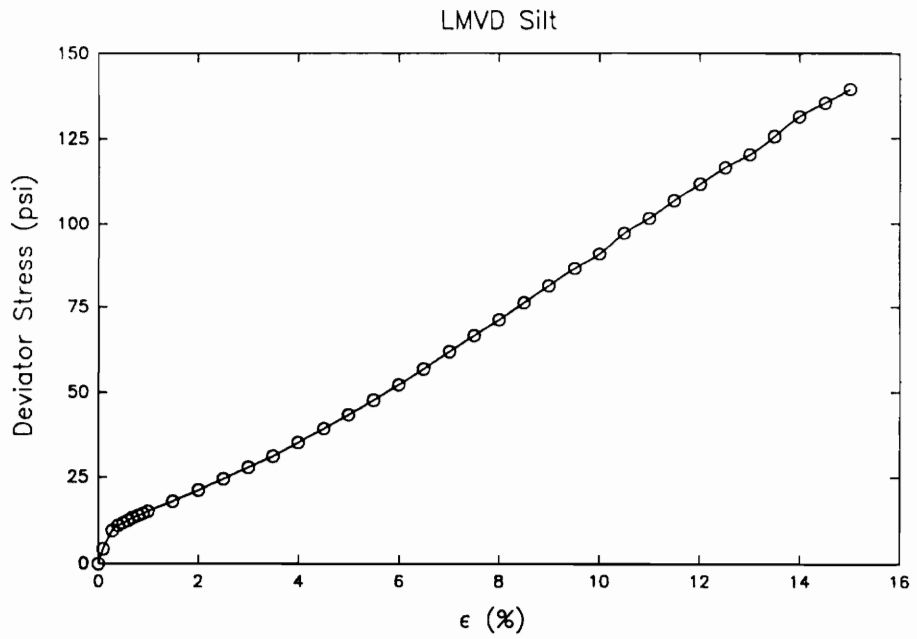

**Figure 3** Deviator Stress-Strain Relationship Measured For CU Triaxial Test On Cape Canaveral Silt (Newhouse, 1990)

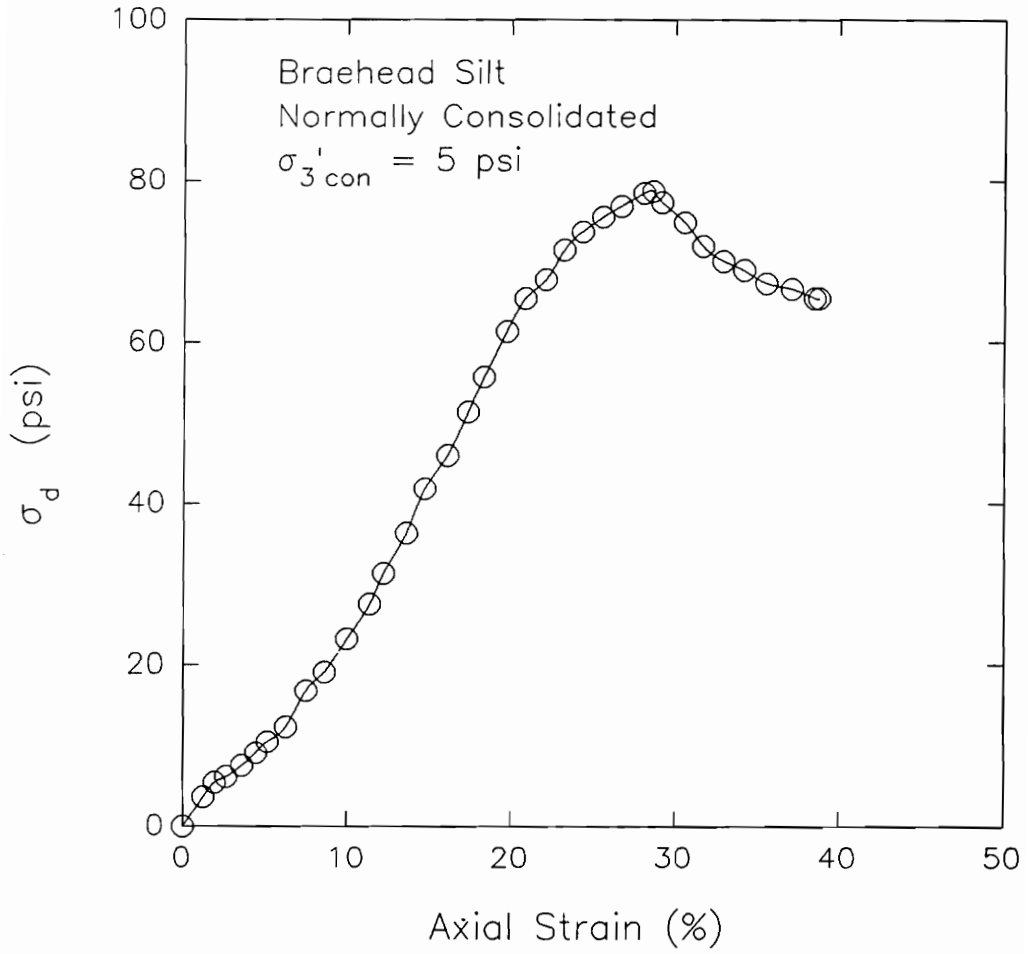

strains. The deviator stress continued to increase following a flatter slope, and did not peak throughout the duration of the test. This condition makes it difficult to define failure. The corresponding effective stress path for this sample is shown in Figure 4. The general trend of the stress path is to approach the  $K_f$  line at small strains, then continue to follow the  $K_f$  line as strains increase. A similar stress-strain behavior is shown in Figure 5, which was measured for a CU triaxial test on LMVD silt (Brandon et al., 1990). It can be seen that the stress-strain diagram followed a flatter slope but never reached a maximum deviator stress. Figure 6 illustrates the stress-strain curve for the reconstituted Braehead silt (Penman, 1953). Although the sample showed a peak in the stress-strain diagram, the maximum deviator stress did not occur until about 28% axial strain.

## CHAPTER 3

### FAILURE CRITERIA

The relationship of the deviator stress and strain measured from undrained triaxial tests on dilative silts usually does not show peak behavior. The deviator stress may continue to increase to strains up to about 30% without showing any strain softening. This makes it difficult to define failure for determining engineering design parameters.

The different failure criteria presented in geotechnical literature include the following:

1. Maximum deviator stress,  $(\sigma_1 - \sigma_3)_{\max}$
2. Maximum principal stress ratio,  $(\sigma_1' / \sigma_3')_{\max}$
3. Maximum pore pressure,  $u_{\max}$ , (Nacci et al, 1970)
4.  $A\text{-bar} = 0$ , (Torrey, 1982)
5. 10% limiting strain (Borgesson, 1981)
6. 15% limiting strain (Duncan and Fleming, 1990)
7.  $\tan(\rho) / \tan(\phi')$  (Senneset, 1990)
8. Reaching the  $K_f$  line.

Figure 7 illustrates the different failure criteria, except limiting strain, plotted on an effective stress path for dilative silts. The selection of the failure criteria depends on the following: a.) the type of test

**Figure 7 Effective Stress Path For A Dilative Silt Showing The Points Corresponding To The Different Failure Criteria**

(drained vs. undrained), b.) the type of soil, and c.) the type of project.

### **Maximum Deviator Stress**

The maximum deviator stress is one of the most common failure criterion applied to triaxial test results. It is applicable to UU, CU, and CD triaxial tests. Difficulties may be encountered when applying this failure criterion to soils possessing dilative properties. When dilative soils are tested in undrained tests, the samples have a tendency to expand, resulting in a decrease in pore pressure. This in turn makes the sample stronger as the strain increases. Because of this behavior, the relationship between the deviator stress and strain may never show a peak at a reasonable range of strains. If it does, the maximum deviator stress occurs at high values of strains. An example of this case is the stress-strain diagram for Braehead silt, shown in Figure 6. Although the stress-strain diagram showed a peak value, the maximum deviator stress did not occur until about 28% axial strain. For samples which show peak behavior at strains greater than about 15%, the specimens are often too deformed for reliable strength determinations.

### **Maximum Principal Stress Ratio**

Maximum principal stress ratio as failure criterion is commonly used for CU triaxial tests. It cannot be applied to UU triaxial tests because pore pressures are not monitored during shearing of the sample, thus there is no knowledge of effective stresses. In CD tests, the maximum pore pressure occurs at the same time as the maximum deviator stress.

Figure 7 illustrates the point on the effective stress path defined by the maximum principal stress ratio. It is represented by the point of tangency of a line drawn from the origin and the effective stress path. For dilative soils characterized by  $\phi' > 0$  and  $c' > 0$ , the maximum principal stress ratio occurs before the stress path reaches the  $K_f$  line. For dilative soils with  $c' = 0$ , the maximum principal stress ratio represents the point where the effective stress path approaches the  $K_f$  line.

### **Maximum Pore Pressure**

D'Andrea (1970) proposed the shear stress at maximum pore pressure as a failure criterion for Rhode Island silt because it provided a unique relationship between shear strength and effective consolidation pressure.

Maximum pore pressure as failure criterion can only be applied to CU triaxial tests. In UU tests, pore

pressures are not known, and in CD tests, change in pore pressure due to application of deviator stress is zero throughout the test. Figure 7 illustrates the point on the effective stress path represented by maximum pore pressure. It can be defined as the point of tangency between the stress path and the tangent line to the stress path oriented at  $45^\circ$  counterclockwise.

#### **A-bar = 0**

Torrey (1982) proposed  $A\text{-bar} = 0$  as a failure criterion to define failure of dilative silts and sands. This failure criterion is applicable to CU tests where pore pressures fall to zero or negative values. It cannot be applied to UU and CD tests. The point of intersection of the line drawn from the effective consolidation pressure oriented at  $45^\circ$  counterclockwise and the effective stress path defines the point at  $A\text{-bar} = 0$ . This is shown in Figure 7.

If failure is defined by  $A\text{-bar} = 0$ , the effective stresses at failure are equal to total stresses. The undrained shear strength,  $S_u$ , could be defined by the equation:

$$S_u = \frac{(\sigma_1 - \sigma_3)_f}{2} \quad (2)$$

For soils having a value of cohesion intercept,  $c'$ , equal to zero, the undrained strength ratio,  $S_u/p$ , can be determined from the effective stress friction angle,  $\phi'$ , by the equation:

$$\frac{S_u}{p} = \frac{\sin \phi'}{1 - \sin \phi'} \quad (3)$$

### Limiting Strains

Limiting strains as failure criteria are applied to triaxial tests were the relationship between the deviator stress and strain does not show a peak behavior or the maximum deviator stress occurs at high strains. This failure criterion is applicable to CU, UU, and CD triaxial tests. The choice of a limiting strain has varied from author to author. Wang et al. (1982) used 5% limiting strain during the investigation of the geotechnical properties of Alaskan silts. Borgesson (1981) used 10% limiting strain to verify the shear strength of inorganic silty soils. Duncan and Fleming

(1990) used 15% limiting strain for the determination of shear strength for Alaskan silts.

### **Tan( $\rho$ )/Tan( $\phi'$ )**

Prof. Kaare Senneset of the University of Trondheim proposed the use of Tan( $\rho$ )/Tan( $\phi'$ ) as a failure criterion.  $\rho$  is defined as the effective stress friction angle measured from the Mohr's circle defined by the effective stresses at any point during the test. For soils with the effective cohesion intercept equal to zero, the maximum value of  $\rho$  would be the same as the effective stress friction angle if failure is defined by maximum principal stress ratio. Therefore, using Tan( $\rho$ )/Tan( $\phi'$ ) as a failure criterion would give the same  $\phi'$  as  $(\sigma_1'/\sigma_3')_{\max}$ .

### **Reaching The $K_f$ Line**

The point where the effective stress path reaches the  $K_f$  line is shown in Figure 7. For dilatent materials with an effective cohesion intercept and effective stress friction angle greater than zero, the point where the stress path approaches the  $K_f$  line usually occurs after the point defined by maximum principal stress ratio. For soils whose effective cohesion intercepts are equal to

zero, the failure criteria defined by  $K_f$  line is approximately the same as the maximum principal stress ratio.

## CHAPTER 4

### TRIAxIAL TESTS ON DIFFERENT SILT SAMPLES

#### ALASKAN SILT

Fleming (1985) tested Alaskan silt from the Beaufort Sea. Both undisturbed and reconstituted samples were tested. The undisturbed samples were taken using 2.8 inches diameter Shelby tubes. The remolded or reconstituted samples were prepared by slurry consolidation. The soil was dried and pulverized and passed through the #16 sieve. The dried soil was mixed with water to a water content of approximately 40%. The slurry was then consolidated one-dimensionally using the consolidometer shown in Figure 8. A typical consolidation curve obtained for a reconstituted sample is shown in Figure 9. The coefficient of consolidation,  $c_v$ , determined from the consolidation tests of the reconstituted samples ranged from 270 ft<sup>2</sup>/year to 780 ft<sup>2</sup>/year. These values are close to those determined for undisturbed specimens (170 ft<sup>2</sup>/year to 850 ft<sup>2</sup>/year).

#### Index Properties of Alaskan Silt

Figure 10 shows the natural water contents and dry densities for the silt samples obtained from an offshore site in the Beaufort Sea. Grain size analyses were performed on undisturbed samples and reconstituted

Figure 8 Consolidometer Used To Prepare The Reconstituted Samples of Alaskan Silt (Fleming, L.N., 1985)

Figure 9 Consolidation Curve Measured For The Reconstituted Samples of Alaskan Silt (Fleming, 1985)

Figure 10 Generalized Subsurface Profile For Offshore Site In Beaufort Sea (Fleming, 1985)

samples. As shown in Figure 11, the average grain size distribution curve for the reconstituted samples plots well within the range of grain size distribution curves for the unmixed samples. The grain size components are given in Table 1. Shown in Figure 12 is a plasticity chart for the Alaskan silt. Most samples plot close to the A-line, with the majority of the samples classifying as ML according to ASTM D-2487-85.

#### **Isotropically Consolidated Undrained Triaxial Tests On Reconstituted Alaskan Silt**

A series of isotropically consolidated undrained triaxial tests were performed on reconstituted Alaskan silt. The samples tested had diameters of 1.40 inches and heights of 3.0 inches. All specimens were initially consolidated in the batch consolidometer to a vertical stress of 14.20 psi. The specimens were then reconsolidated in triaxial cells to isotropic effective consolidation stresses of 14.20, 21.30, and 28.40 psi. Conventional procedures of back pressure saturation were performed to give B values from 0.988 to 0.998. The initial specimen properties are given in Table 2.

The stress-strain curves for the Alaskan silt are shown in Figure 13. Only the specimen consolidated to

| 4              | 31.30                        | 87.80                    |

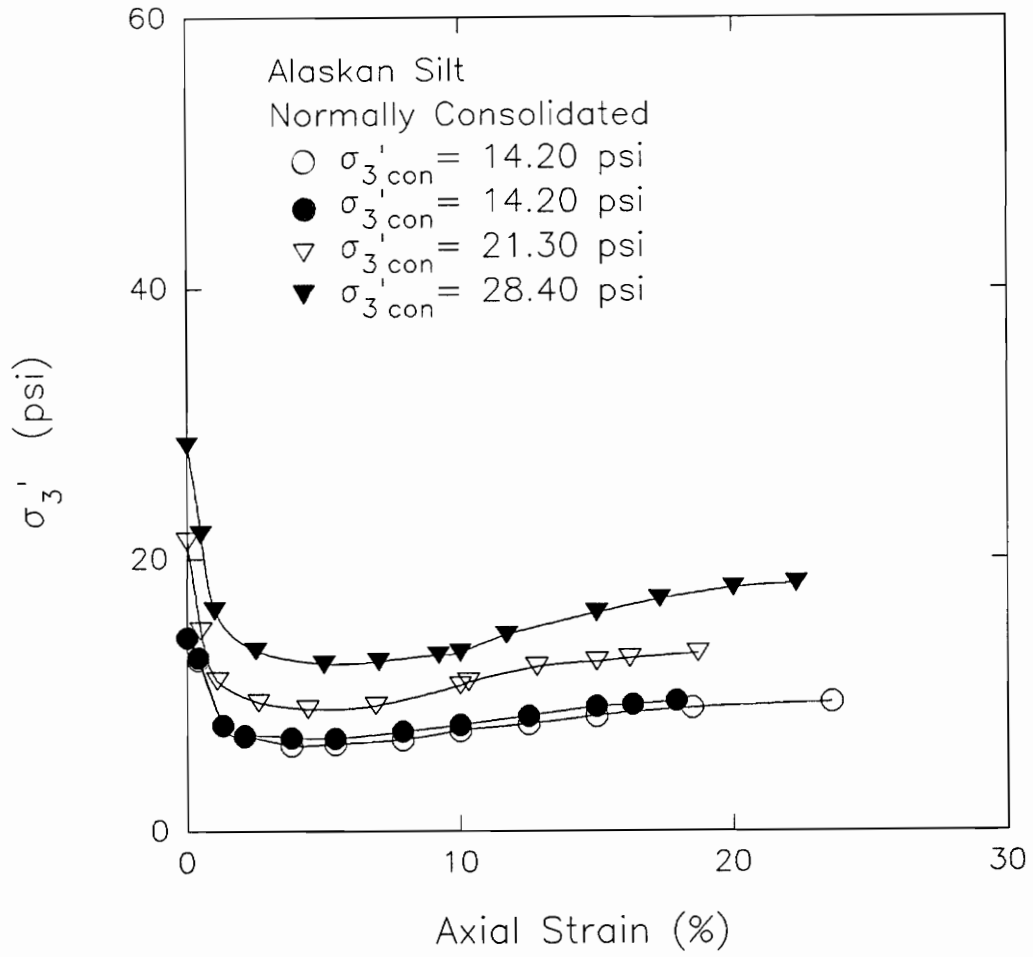

**Figure 13 Deviator Stress-Strain Relationship Measured For The ICU Triaxial Tests On Normally Consolidated Alaskan Silt**

28.40 psi exhibited a peak deviator stress at a strain of about 20%.

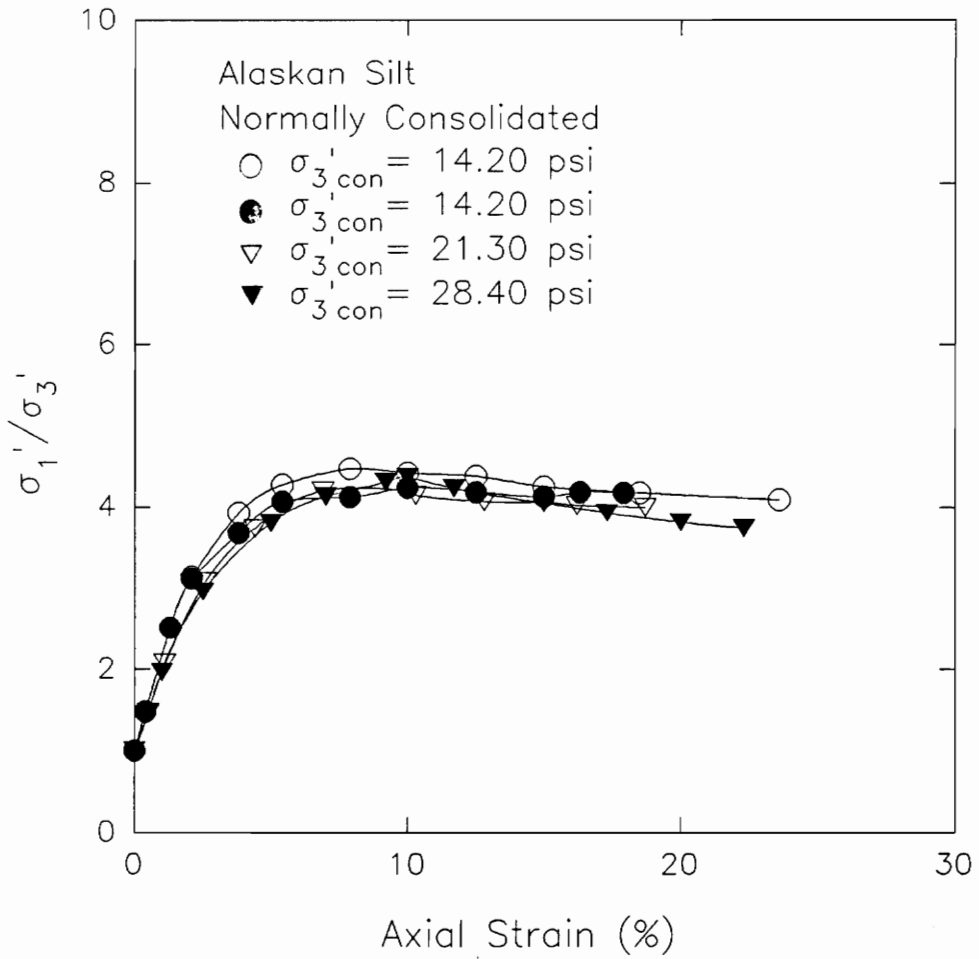

Figures 14 and 15 illustrate the minor effective stress-strain and principal stress ratio-strain relationships for the Alaskan Silt. The principal stress ratio-strain relationship showed small variations with regards to the effective consolidation pressure. Maximum principal stress ratios were attained at strains ranging from 9.60% to 10.50%.

The relationships between  $A\text{-bar}$ -Strain and pore pressure-strain are plotted on Figure 16 and 17 respectively. All samples showed a peak in their pore pressure-strain behavior and then pore pressure decreased as shearing continued. Maximum pore pressures occurred at axial strains ranging from 3% to 4%.

Figure 18 shows the effective stress paths for the Alaskan silt. The stress paths clearly delineate the  $K_f$  line, with an  $\alpha$  value equal to  $31^\circ$ . This corresponds to an effective stress friction angle,  $\phi'$ , equal to  $37^\circ$ .

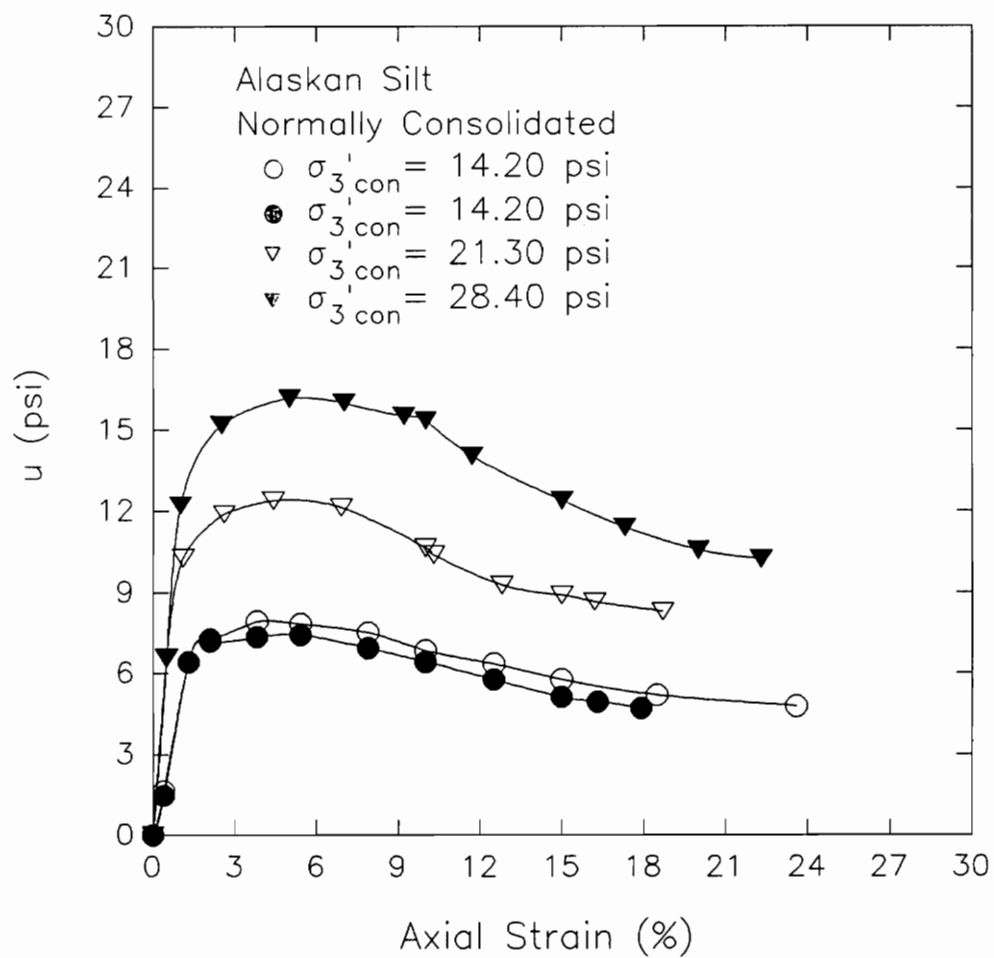

**Figure 14 Minor Effective Stress-Strain Relationship Measured For The ICU Triaxial Tests On Normally Consolidated Alaskan Silt**

**Figure 15 Principal StressRatio-Strain Relationship  
Measured For The ICU Triaxial Tests On Normally  
Consolidated Alaskan Silt**

**Figure 17 Pore Pressure-Strain Relationship Measured For ICU Triaxial Tests On Normally Consolidated Alaskan Silt**

**Figure 18 Effective Stress Paths Measured For The ICU Triaxial Tests On Normally Consolidated Alaskan Silt**

### **Effective Stress Interpretation of ICU Tests On Reconstituted Alaskan Silt**

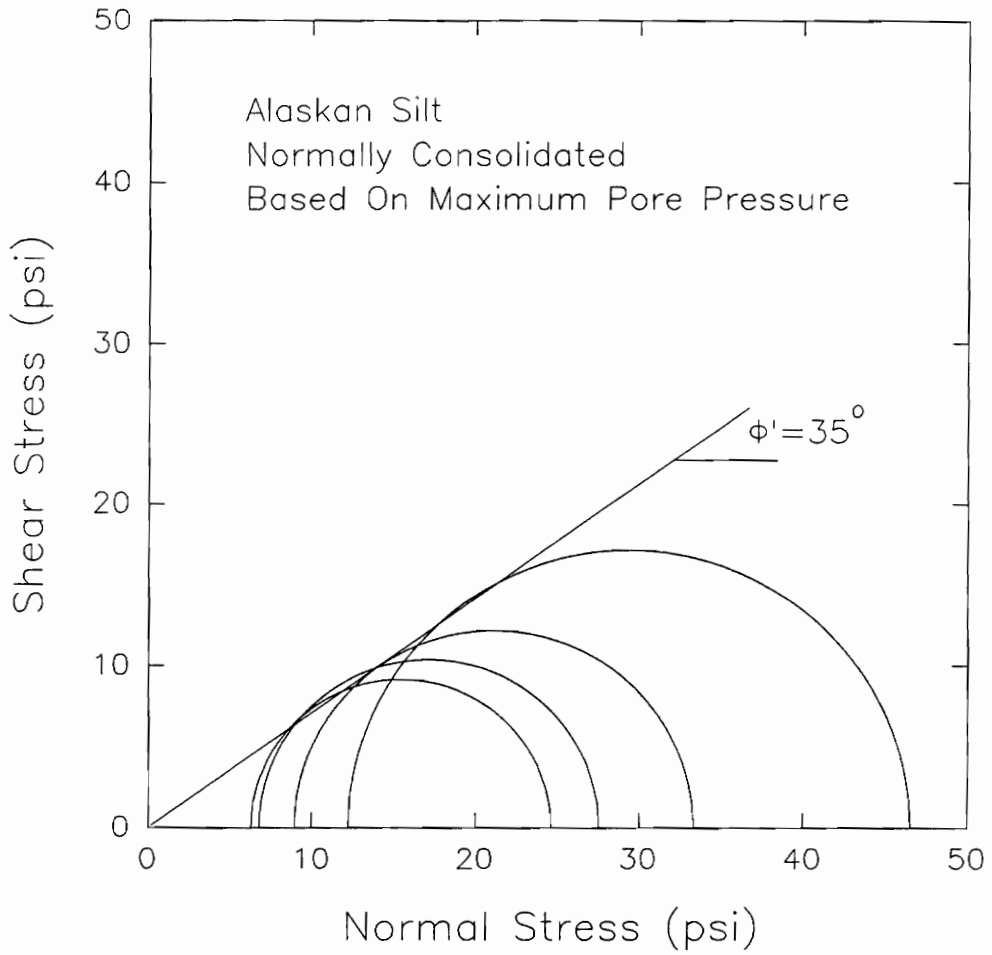

All the specimens reached maximum pore pressures at strains from 3% to 4%. Effective Mohr's circles, based on maximum pore pressure as a failure criterion, are plotted in Figure 19. Constraining the effective cohesion,  $c'$ , intercept to zero, an effective stress friction angle,  $\phi'$ , of  $35^\circ$  was calculated.

Only the specimen consolidated to 28.40 psi reached a maximum deviator stress during the test and this was attained at strain of 20%. The Mohr's circle for this test is shown in Figure 20, with an effective stress friction angle,  $\phi'$ , of  $36^\circ$ .

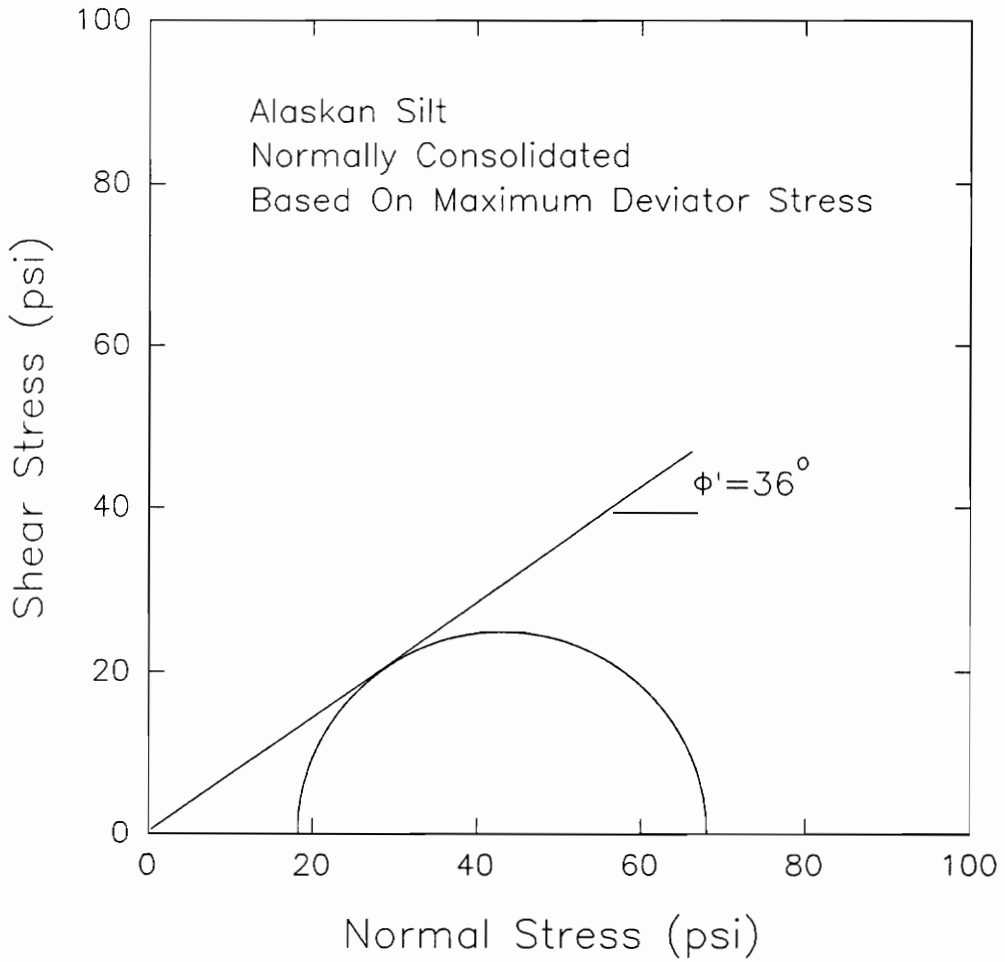

Using the maximum principal stress ratio as failure criterion, the Mohr's circles are plotted on Figure 21. The samples reached maximum principal stress ratio at strains of 9.60% to 10.50%. Again, constraining the effective cohesion intercept to zero, the envelope gives an effective stress friction angle of  $38^\circ$ .

Limiting strains as failure criteria can also be applied to this test data. Mohr's circles for 10% limiting strain are shown in Figure 22. The envelope gives an effective stress friction angle of  $38^\circ$ . Based on 15% limiting strain, as shown in Figure 23, the resulting friction angle is  $38^\circ$ .

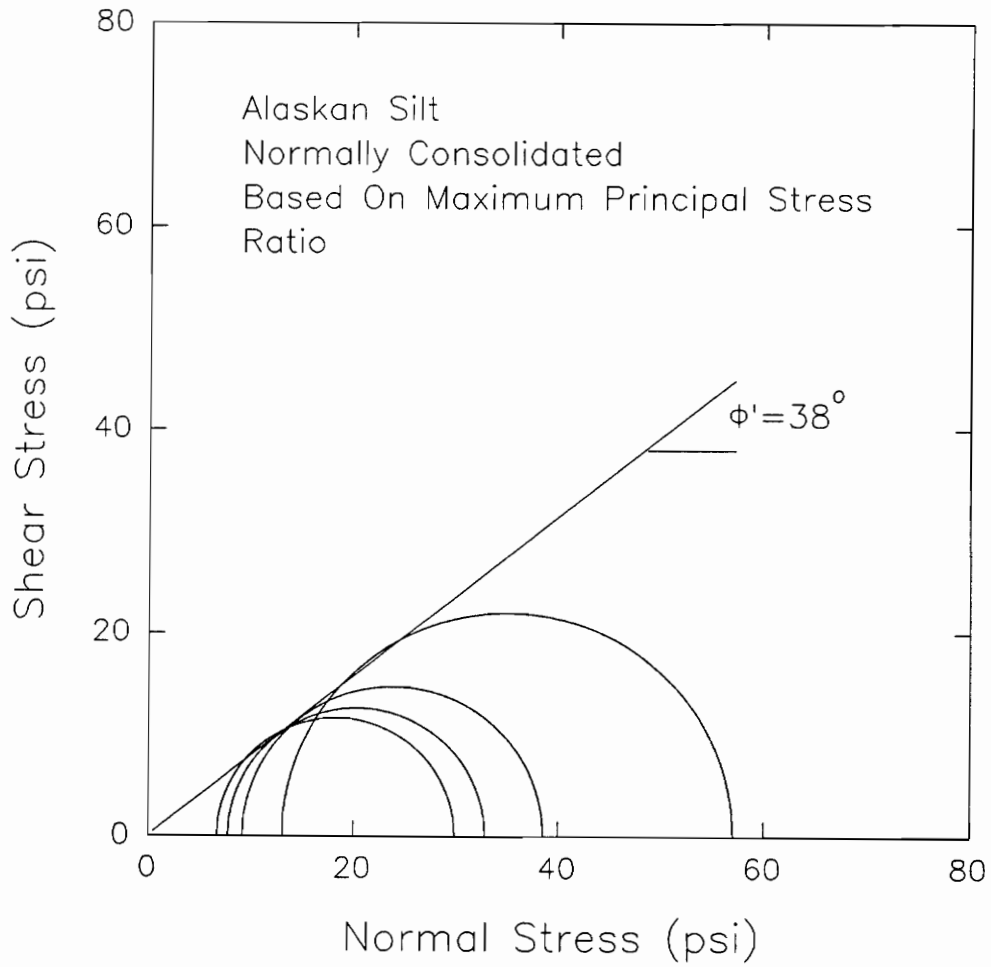

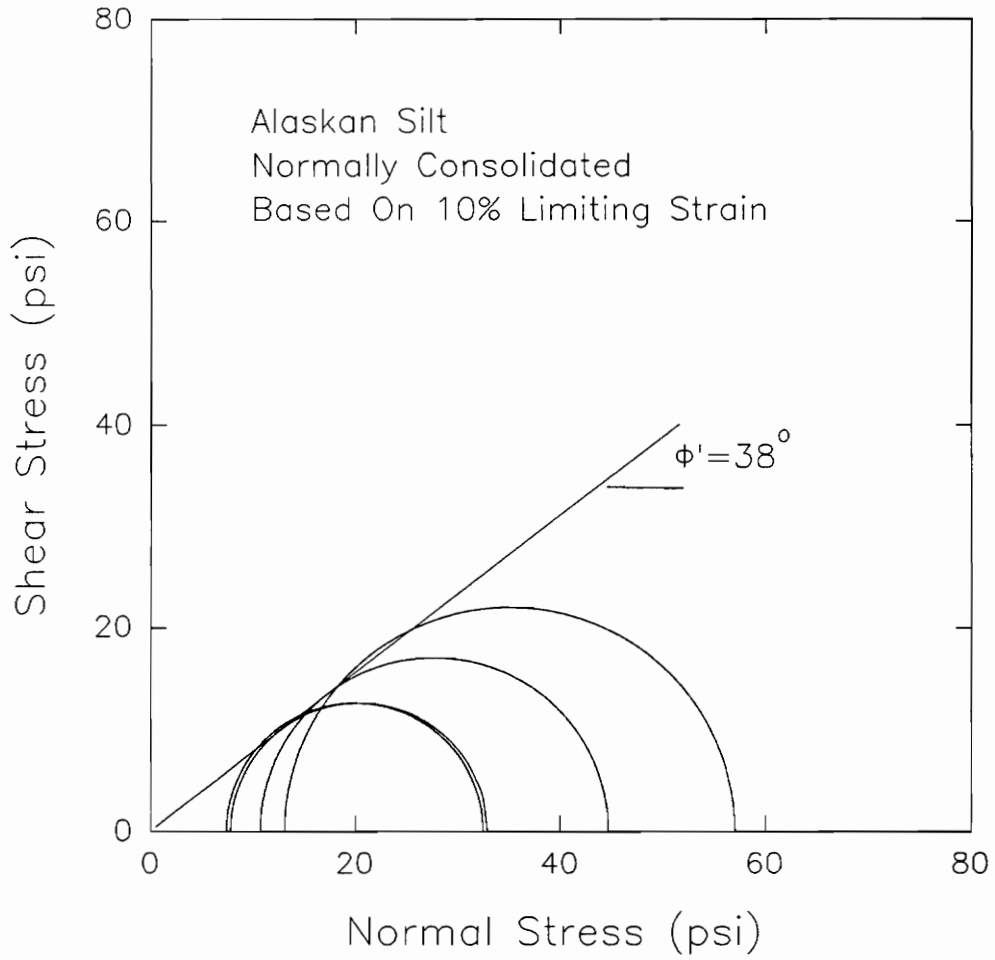

**Figure 19 Effective Stress Mohr's Circles Measured For The ICU Triaxial Tests On Normally Consolidated Alaskan Silt For Failure Based On Maximum Pore Pressure**

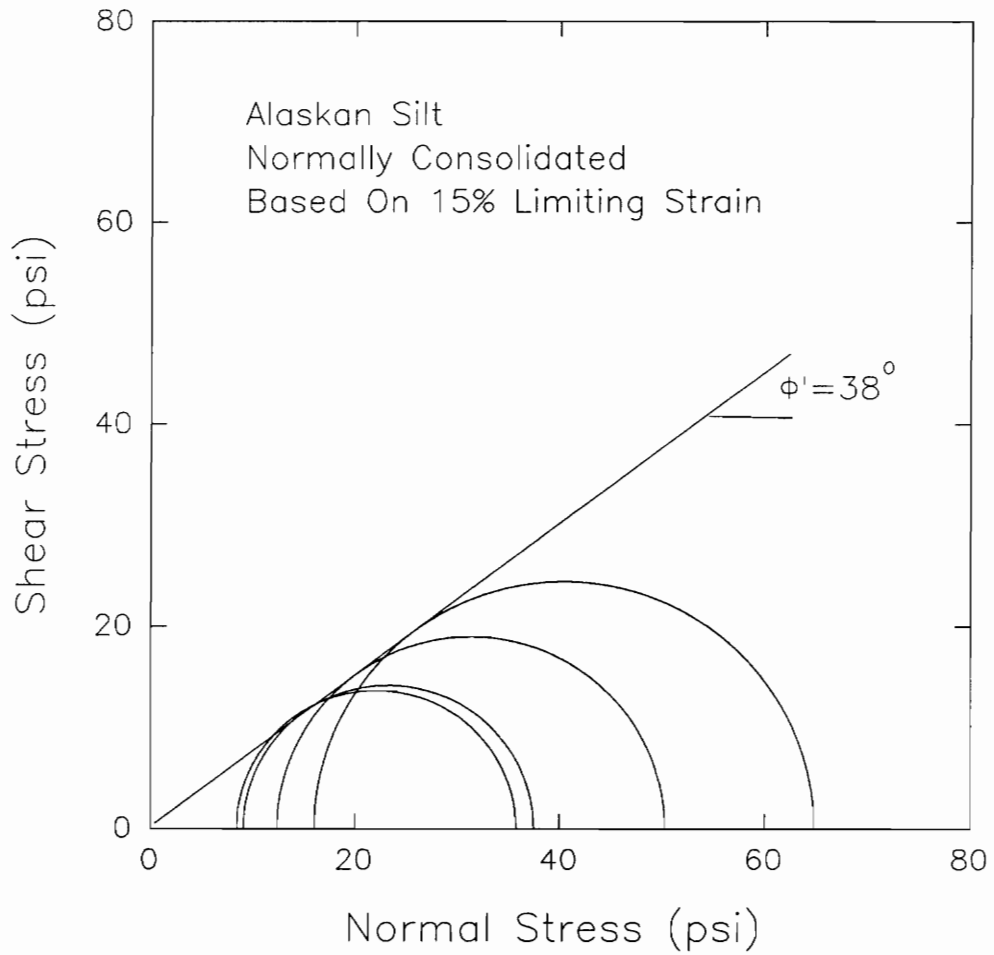

**Figure 20 Effective Stress Mohr's Circles Measured For The ICU Triaxial Tests On Normally Consolidated Alaskan Silt For Failure Based On Maximum Deviator Stress**

**Figure 21 Effective Stress Mohr's Circles Measured For The ICU Triaxial Tests On Normally Consolidated Alaskan Silt For Failure Based On Maximum Principal Stress Ratio**

**Figure 22 Effective Stress Mohr's Circles Measured For The ICU Triaxial Tests On Normally Consolidated Alaskan Silt For Failure Based On 10% Limiting Strain**

**Figure 23 Effective Stress Mohr's Circles Measured For The ICU Triaxial Tests On Normally Consolidated Alaskan Silt For Failure Based On 15% Limiting Strain**

Since all specimens had positive pore pressures throughout the tests,  $A\text{-bar}$  equal to zero as a failure criterion could not be applied.

A summary of effective stress friction angle based on different failure criteria is given in Table 3. The resulting values of the effective stress friction angles for the samples ranged from  $36^\circ$  to  $38^\circ$ .

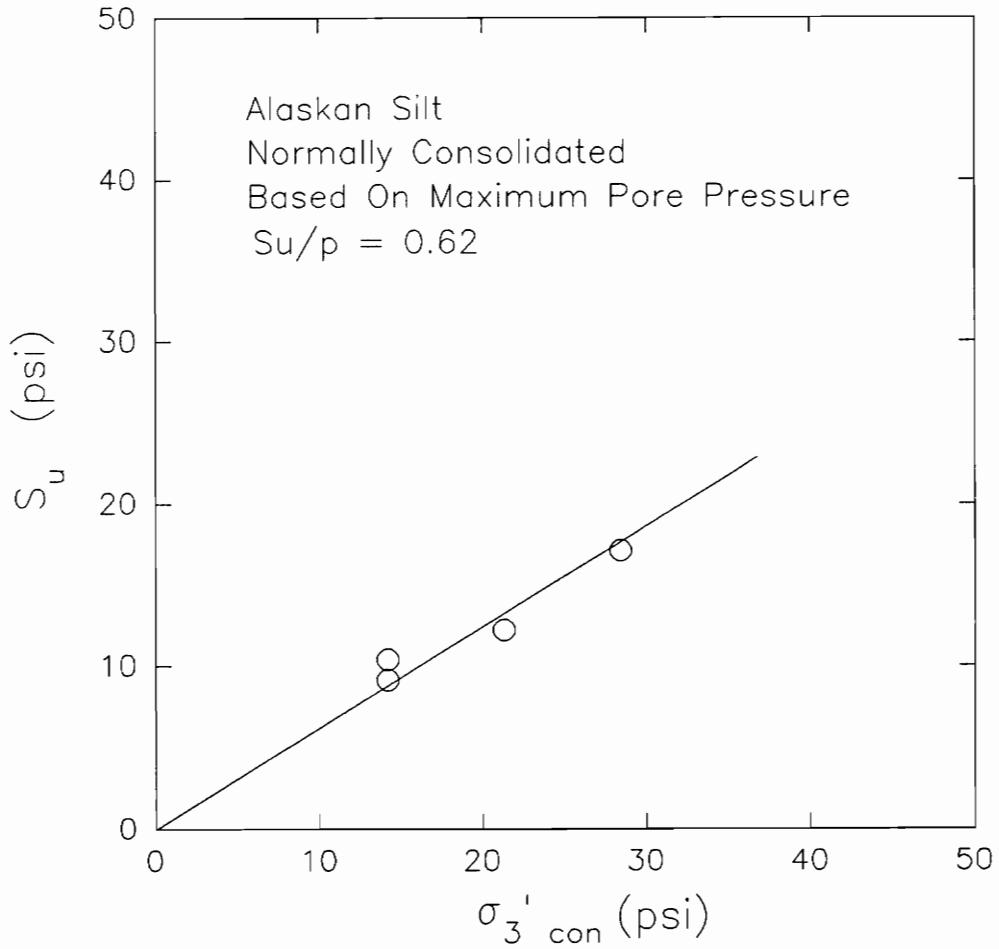

#### **Total Stress Interpretation of ICU Tests On Reconstituted Alaskan Silt**

Shown in Figure 24 is the undrained strength and effective consolidation pressure relationship based on maximum pore pressure. The undrained strength ratio,  $S_u/p$ , can be defined by determining the slope of the line drawn from the origin through the data points. The value of  $S_u/p$  derived based on maximum pore pressure is equal to 0.62. Note that this value is a good estimate due to little scatter in the results.

Using maximum deviator stress as failure criterion to define the undrained strength ratio for this test gave a biased estimate because only one sample was represented. The undrained strength-consolidation

**Table 3 Effective Stress Friction Angle For Reconstituted Samples of Alaskan Silt At Different Failure Criteria**

| Failure Criteria            | $\phi'$<br>(Degrees) | Average Strain To Failure (%) |
|-----------------------------|----------------------|-------------------------------|
| $U_{\max}$                  | 35                   | 4.0                           |
| Max $(\sigma_1 - \sigma_3)$ | 36                   | 20.0                          |
| Max $\sigma_1'/\sigma_3'$   | 38                   | 10.0                          |

**Figure 24 Undrained Shear Strength-Effective Consolidation Pressure Relationship Measured For The ICU Triaxial Test On Normally Consolidated Alaskan Silt For Failure Based On Maximum Pore Pressure**

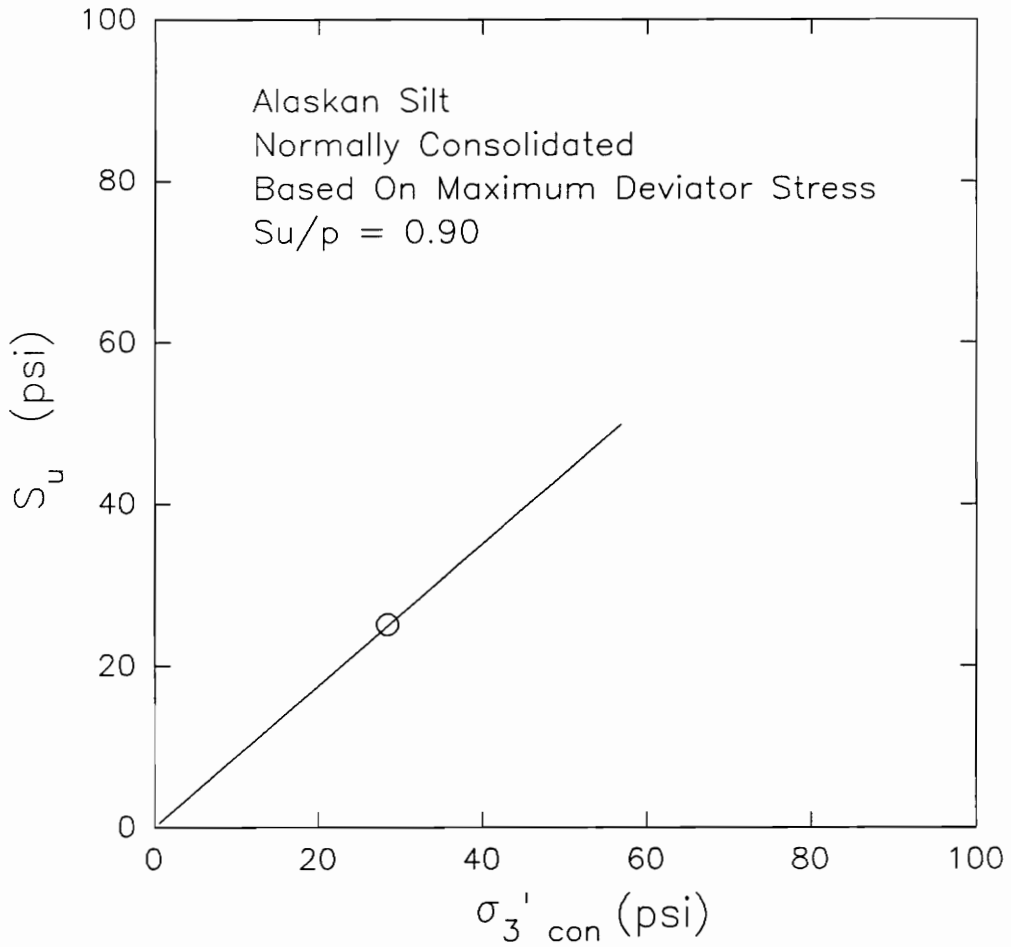

pressure relationship is shown in Figure 25 which gives a value of  $S_u/p$  of 0.9.

Figure 26 shows the undrained shear strength and consolidation pressure relationship based on maximum principal stress ratio. The data exhibit little scatter, and the undrained strength ratio,  $S_u/p$ , is approximately equal to 0.81.

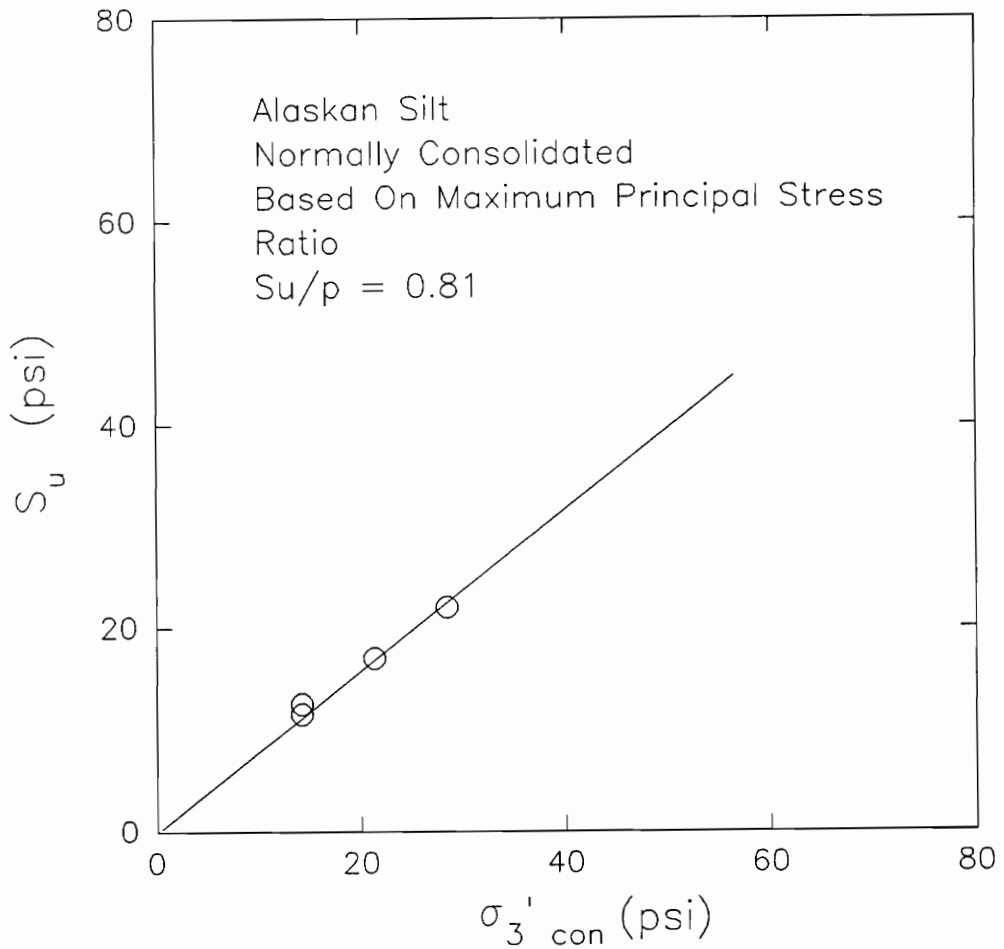

Figures 27 and 28 show the undrained strength ratio based on 10% and 15% limiting strains, respectively. The estimated  $S_u/p$  for the 10% limiting strain is 0.81 and 0.88 for 15% limiting strain.

As discussed in the effective stress analysis,  $A\text{-bar}$  equal to zero cannot be applied because the pore pressures remained positive during the test.

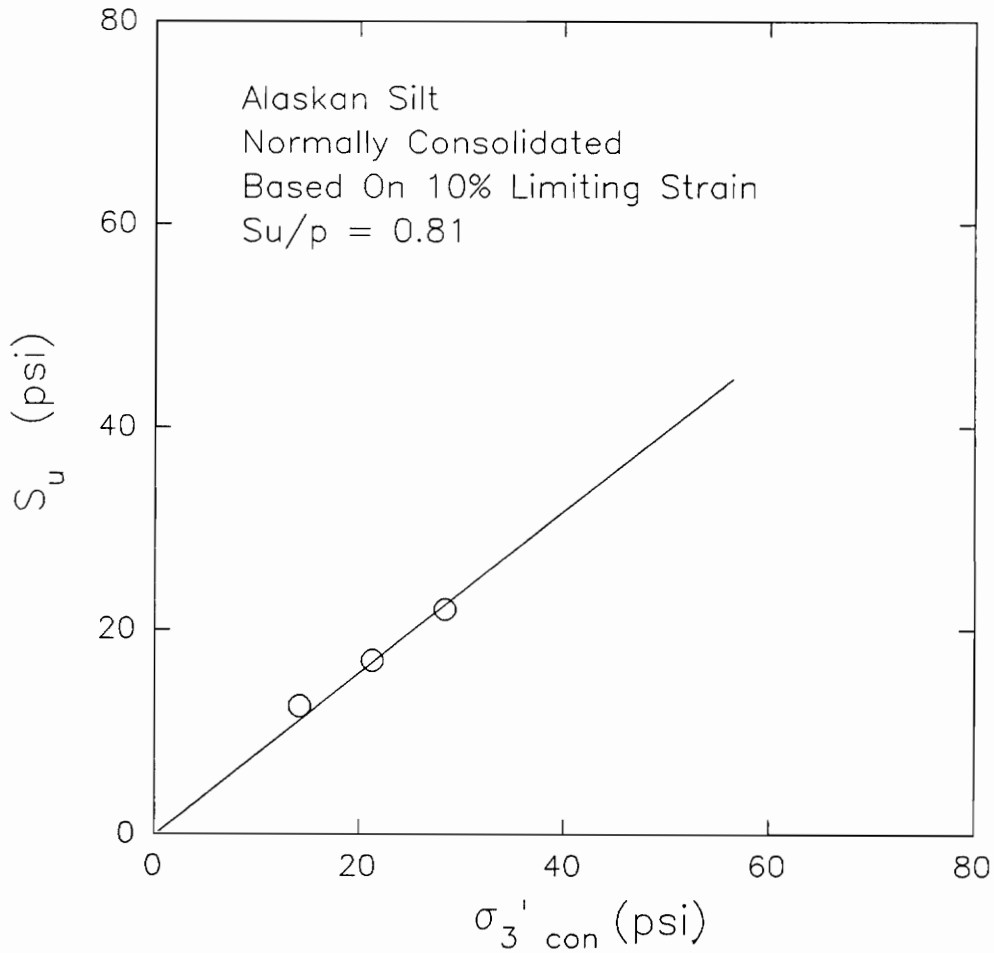

A summary of the undrained strength ratios determined for the samples is given in Table 4. The range of  $S_u/p$  for the different failure criteria is 0.81 to 0.90, except for  $S_u/p$  based on maximum pore pressure which gave the lowest value of 0.62. Using Skempton's correlation of  $S_u/p$ , expressed as,  $S_u/p = 0.11 + 0.0037 (PI)$ , the undrained shear strength can be estimated based on the plasticity index. This correlation gives an  $S_u/p$  equal to 0.13.

### Unconsolidated Undrained Triaxial Tests On Reconstituted Alaskan Silt.

Four UU Triaxial tests were performed on reconstituted samples of Alaskan silt. The sample preparation procedure was identical to the one used for the ICU tests. Table 5 shows the properties of the UU test specimens of the reconstituted Alaskan silt. The cell pressures applied were 7.10 psi, 14.20 psi, 21.30 psi, and 28.40 psi. The loading rate during the test was 0.55 lb/minute.

Figure 29 shows the deviator stress-strain relationship measured during the test. None of the samples exhibited a peak deviator stress in the range of the strains used, thus precluding the use of maximum deviator stress as a failure criterion. In this case, failure could be defined by limiting strains.

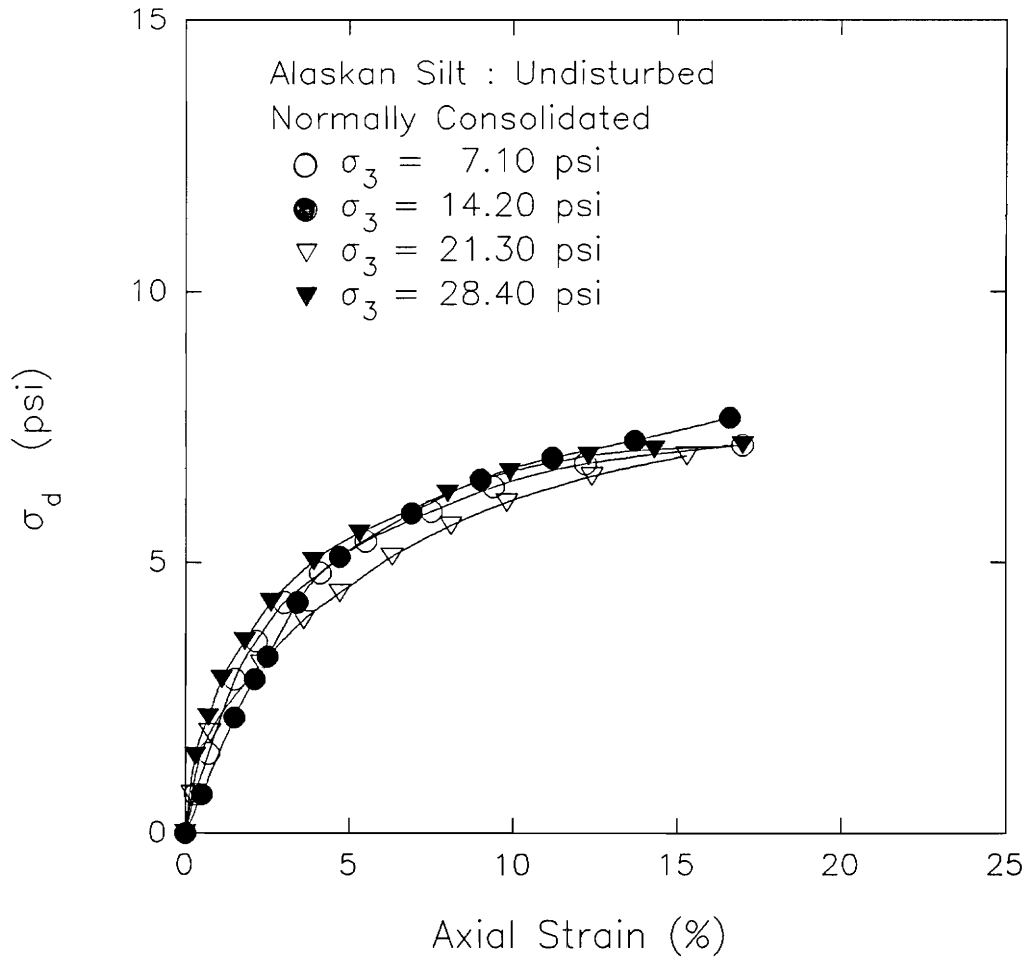

The Mohr's circles using 10% limiting strain as failure criterion are plotted in Figure 30. Using a  $\phi_u=0$  interpretation, the undrained strength,  $S_u$ , is about 3.20 psi. This gives an undrained strength ratio,  $S_u/p$ , of 0.23 since the samples were initially consolidated to 14.20 psi.

Another failure criteria proposed by Fleming (1985) is 15% limiting strain. Based on this failure criteria,

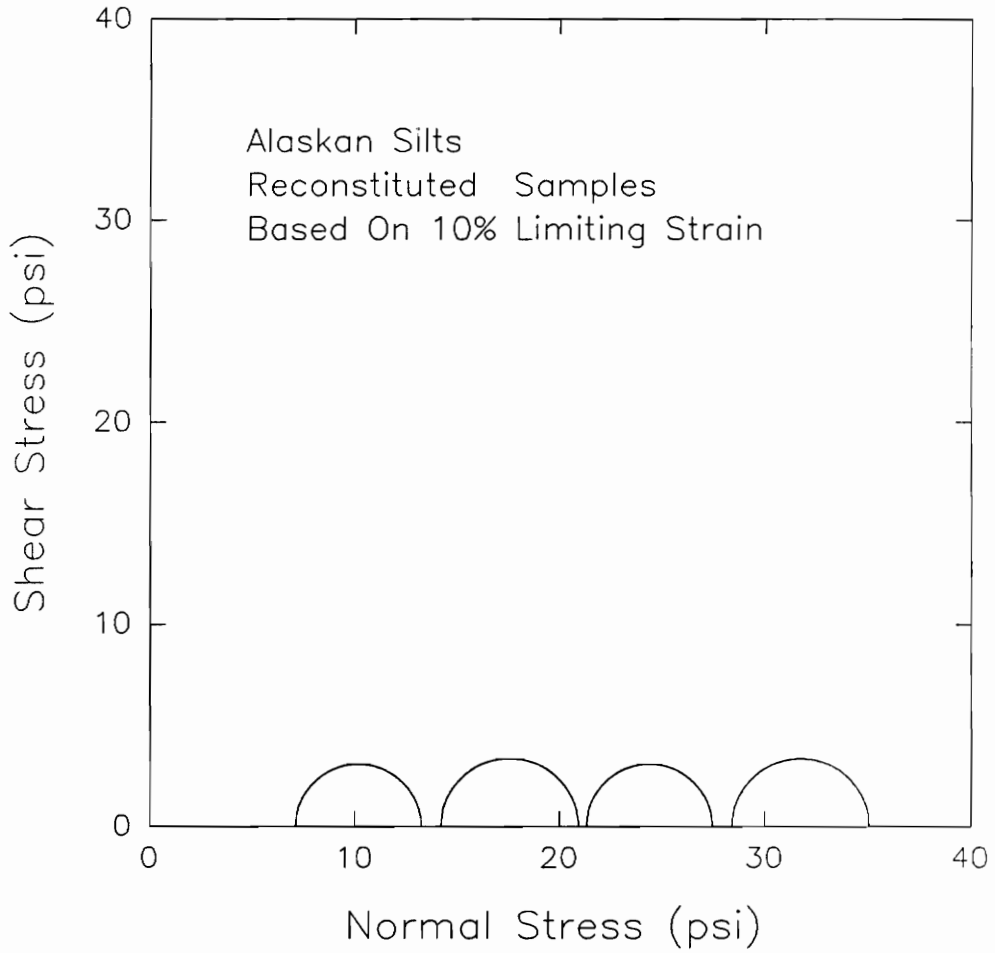

**Table 5 Properties of UU Tests Samples Of Reconstituted Alaskan Silt**

| Test Number | Water Content (%) | Cell Pressure (psi) | Dry Density (pcf) | OCR |
|-------------|-------------------|---------------------|-------------------|-----|
| 1           | 7.10              | 33.60               | 86.60             | 1   |
| 2           | 14.20             | 33.20               | 84.70             | 1   |
| 3           | 21.30             | 33.20               | 85.30             | 1   |
| 4           | 28.40             | 34.20               | 85.30             | 1   |

**Figure 29 Deviator Stress-Strain Relationship Measured For UU Triaxial Tests On Reconstituted Alaskan Silt**

**Figure 30 Mohr's Circles Measured For UU Triaxial Tests  
On Reconstituted Alaskan Silt For Failure Based  
On 10% Limiting Strain**

the Mohr's circles are plotted in Figure 31. Using  $\phi_u = 0$  method, the resulting undrained shear strength is 3.60 psi. This gives an undrained strength ratio,  $S_u/p$ , of 0.25.

Table 6 summarizes the values of  $S_u/p$  ratios for different failure criteria measured for the UU triaxial tests for the samples.

**Figure 31 Mohr's Circles Measured For UU Triaxial Tests On Reconstituted Alaskan Silt For Failure Based On 15% Limiting Strain**

**Measured For UU Triaxial Test On Alaskan Silt**

| <b>Failure Criteria</b>        | <b>S<sub>u</sub>/p</b> |
|--------------------------------|------------------------|
| $(\sigma_1 - \sigma_3)_{\max}$ | N/A                    |
| 10% Limiting Strain            | 0.23                   |
| 15% Limiting Strain            | 0.25                   |

## **Braehead Silt**

Penman (1953) performed triaxial tests on saturated silt specimens from Braehead Power Station, Scotland. The samples used were reconstituted from dry samples obtained from borings on the site. De-aired water was added to the dry silt to form a slurry. A more detailed material and sample preparation are discussed in reference (11).

### **Index Properties of Braehead Silt**

Figure 32 shows the grain size distribution curve for Braehead silt. The grain size components are given in Table 7. The sample consists mostly of silt particles with grain size diameter less than 0.074 mm and greater than 0.003 mm. No clay size components are present in the sample. The specific gravity of the specimen is 2.71 and the liquid limit is 24.6%.

### **Consolidated Undrained Triaxial Test On Normally Consolidated Sample of Reconstituted Braehead Silt.**

One CU triaxial test was conducted on a reconstituted sample of Braehead silt. The sample had a diameter of 1.50 inches and was 3.50 inches long. The displacement rate used in the test was 0.025 inch per minute which corresponds to about 1% strain per minute.

**Figure 32 Grain Size Distribution Curve For Braehead Silt**

**Table 7 Grain Size Components of Braehead Silt**

| <b>Component</b> | <b>Amount</b> |
|------------------|---------------|
| % Sand           | 18.0%         |
| % Silt           | 82.0%         |
| % Clay           | 0 %           |

The sample was fully saturated prior to shearing. The effective consolidation pressure used during the test was 5 psi.

Shown in Figures 33 and 34 are the deviator stress-strain and minor effective stress-strain relationships. Even though the stress-strain diagram reached a maximum value, the peak does not occur until a strain of about 28%. The maximum value of the minor effective stress occurred at the same strain as the maximum deviator stress.

Figure 35 illustrates the principal stress ratio-strain relationship for this test. The principal stress ratio had a maximum value of 3.90 at a strain of 7.50%.

Figures 36 and 37 show the  $\bar{A}$ -strain and pore pressure-strain relationships. The pore pressure during straining reached a maximum value of 2.30 psi at a strain of about 2%.

The behavior of the pore pressure is reflected in the effective stress path shown in Figure 38. When pore pressure started decreasing, the stress path approached the  $K_f$  line and continued to climb the  $K_f$  line up to a strain of 28%. When the pore pressure started increasing again, the stress path reversed direction where  $p'$  and  $q$  both decreased. The measured angle  $\alpha$  for the  $K_f$  line is

**Figure 33 Deviator Stress-Strain Relationship Measured For CU Triaxial Test On Reconstituted Sample of Braehead Silt**

CU Triaxial Test On Reconstituted Sample of  
Braehead Silt**

**Figure 38 Effective Stress Path Measured For CU Triaxial Test On Reconstituted Sample of Braehead Silt**

30°, which corresponds to an effective stress friction angle,  $\phi'$ , equal to 35°.

#### **Effective Stress Interpretation of The CU Triaxial Test On Reconstituted Sample of Braehead Silt.**

The effective stress interpretation for Braehead silt is done in the same manner as the previous silt samples.

Figure 39 shows the Mohr's circles based on maximum pore pressure as failure criterion. Constraining the effective cohesion intercept to zero, the value of  $\phi'$  calculated is equal to 31°.

Figure 40 illustrates the Mohr's circle for failure based on maximum deviator stress. A  $\phi'$  of 37° is calculated for this failure criterion.

Shown in Figure 41 is the Mohr's circle based on maximum principal stress ratio. The value of the effective stress friction angle calculated is 36°.

Figures 42 and 43 illustrate the Mohr's circles for failure based on 10% and 15% limiting strains. These failure criteria gave values of effective stress friction angles equal to 35° for 10% limiting strain and 36° for 15% limiting strain.

**Figure 39 Effective Stress Mohr's Circle Measured For CU Triaxial Test On Reconstituted Sample of Braehead Silt For Failure Based On Maximum Pore Pressure**

**Figure 40 Effective Stress Mohr's Circle Measured For CU Triaxial Test On Reconstituted Sample of Braehead Silt For Failure Based On Maximum Deviator Stress**

**Figure 41 Effective Stress Mohr's Circle Measured For CU Triaxial Test On Reconstituted Sample of Braehead Silt For Failure Based On Maximum Principal Stress Ratio**

**Figure 42 Effective Stress Mohr's Circle Measured For CU Triaxial Test On Reconstituted Sample of Braehead Silt For Failure Based On 10% Limiting Strain**

**Figure 43 Effective Stress Mohr's Circle Measured For CU Triaxial Test On Reconstituted Sample of Braehead Silt For Failure Based On 15% Limiting Strain**

The Mohr's circle using  $\bar{A}$  equal to zero failure criterion is shown in Figure 44. The effective stress friction angle calculated is  $34^\circ$ .

A summary of the values of the effective stress friction angles for different failure criteria are given in Table 8. The lowest value of  $\phi'$  was obtained using maximum pore pressure as failure criterion. The average  $\phi'$  from the different failure criteria, except  $u_{\max}$ , is equal to  $35^\circ$  which is the same  $\phi'$  calculated from the effective stress path.

#### **Total Stress Interpretation For CU Triaxial Test On Reconstituted Sample of Braehead Silt**

The values of the undrained strength ratios could be evaluated using the CU test results for the reconstituted Braehead silt.

Figure 45 shows the relationship between the undrained strength and effective consolidation pressure for failure based on maximum pore pressure. Defining  $S_u/p$  as the slope of the line drawn from the origin to the data point, the undrained strength ratio calculated is equal to 0.55.

Shown in Figure 46 is the  $S_u/p$  ratio determined using maximum deviator stress as failure criterion. The value of  $S_u/p$  calculated is 7.80.

**Figure 44 Effective Stress Mohr's Circle Measured For CU Triaxial Test On Reconstituted Sample of Braehead Silt For Failure Based On  $A\text{-bar}=0$**

**Table 8 Effective Stress Friction Angle At Different Failure Criteria For Braehed Silt**

| <b>Failure Criteria</b>             | <b><math>\phi'</math><br/>(Degrees)</b> | <b>Average<br/>Strain To<br/>Failure (%)</b> |
|-------------------------------------|-----------------------------------------|----------------------------------------------|
| $u_{\max}$                          | 31                                      | 2%                                           |
| $\text{Max}(\sigma_1 - \sigma_3)$   | 37                                      | 28%                                          |
| $\text{Max}(\sigma_1' / \sigma_3')$ | 36                                      | 7.5%                                         |
| 10% Limiting Strain                 | 35                                      | 10%                                          |
| 15% Limiting Strain                 | 36                                      | 15%                                          |
| A-bar = 0                           | 34                                      | 7.5%                                         |

**Figure 45 Undrained Shear Strength-Effective Consolidation Pressure Relationship Measured For CU Triaxial Test On Reconstituted Sample of Braehead Silt For Failure Based On Maximum Pore Pressure**

**Figure 46 Undrained Shear Strength-Effective Consolidation Pressure Relationship Measured For CU Triaxial Test On Reconstituted Sample of Braehead Silt For Failure Based On Maximum Deviator Stress**

Values of the undrained strength ratios based on 10% and 15% limiting strains are shown in Figures 48 and 49 respectively.  $S_u/p$  ratios calculated are 2.30 for 10% limiting strain and 4.20 for 15% limiting strain.

Figure 50 shows the  $S_u/p$  based on  $A\text{-bar}$  equal to zero. An  $S_u/p$  of 1.20 was determined using this failure criterion.

Table 9 summarizes the  $S_u/p$  ratios measured for different failure criteria. Similar with the previous silt samples analysed, the maximum pore pressure failure criterion gave the lowest value of  $S_u/p$ . Skempton's correlation of  $S_u/p$  cannot be applied to this test because a plastic limit test was not performed on the sample.

## **Cape Canaveral Silt**

Newhouse (1990) tested silt specimens from Cape Canaveral, Florida. Undisturbed samples of silts were obtained from the site at depths of 47 feet to 49 feet below ground surface. The initial properties of the specimens are given in Table 10. The specimens were described as non-plastic gray sandy silts, which classify as ML according to the Unified Soil Classification System.

### **Consolidated Undrained Triaxial Test On Overconsolidated Undisturbed Sample of Cape Canaveral Silt**

One CU test was performed on an undisturbed sample of Cape Canaveral silt. The initial properties of the sample for CU test are given in Table 11. The effective consolidation pressure used for the triaxial test was 14.20 psi. A consolidation test was also performed on a specimen from the same sampling tube. From the consolidation curve shown in Figure 51, the sample had a  $C_r$  of 0.008 and a  $C_c$  equal to 0.10. The past consolidation pressure of the material ranges from 60 psi to 90 psi. This corresponds to an overconsolidation ratio that ranges from 4.2 to 6.3. The strain rate used for the

**Table 10 Initial Properties of Cape Canaveral Silt**

|                      |          |
|----------------------|----------|
| Water Content        | 40.9 %   |
| Degree of Saturation | 100.0 %  |
| Dry Density          | 82.9 pcf |
| Void Ratio           | 0.995    |

**Table 11 Properties of CU Triaxial Specimens for Cape  
Canaveral Silt**

|                      |          |
|----------------------|----------|
| Water Content        | 36.0 %   |
| Dry Density          | 84.6 pcf |
| Void Ratio           | 0.959    |
| Degree of Saturation | 99.8 %   |

**Figure 51 Consolidation Curve For Cape Canaveral Silt (Newhouse, 1990)**

test was 1.10% per hour. Normal procedures of back pressure saturation were done to insure that the sample was saturated prior to shearing.

Figure 52 illustrates the deviator stress-strain relationship for the specimen. The deviator stress increased rapidly at small strains. The stress-strain diagram exhibited a distinct break at a strain of about 1%. After a steep portion, the stress-strain diagram followed a flatter slope but never peaked throughout the test. This stress-strain behavior is due to the dilative properties of the soil sample.

Figures 53 and 54 illustrate the minor effective stress-strain and principal stress ratio-strain relationships. The sample had a maximum principal stress ratio of 4.3 at a strain of about 8.5%.

Shown in Figures 55 and 56 are the  $A$ -bar-strain and pore pressure-strain relationships. The maximum pore pressure (minimum  $\sigma_3'$ ) was reached at a strain of about 1.7%. After reaching a peak value, it then continued to decrease until a strain of about 20%.

Figure 57 illustrates the effective stress path for the sample. The stress path clearly defines the  $K_f$  line with an  $\alpha$  value equal to  $32^\circ$ . This corresponds to an effective stress friction angle,  $\phi'$ , equal to  $38.5^\circ$ .

**Figure 52** Deviator Stress-Strain Relationship Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample of Cape Canaveral Silt

**Figure 53** Minor Effective Stress-Strain Relationship Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample Of Cape Canaveral Silt

**Figure 54** Principal Stress Ratio-Strain Relationship Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample Of Cape Canaveral Silt

**Figure 55 A-bar-Strain Relationship Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample Of Cape Canaveral Silt**

**Figure 56** Pore Pressure-Strain Relationship Measured For  
CU Triaxial Test On Overconsolidated  
Undisturbed Sample Of Cape Canaveral Silt

**Figure 57** Effective Stress Path Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample Of Cape Canaveral Silt

**Effective Stress Interpretation of The CU Triaxial Test  
On Overconsolidated Undisturbed Sample of Cape Canaveral  
Silt**

All failure criteria could be applied to the CU test results on the sample, except that based on maximum deviator stress.

Figure 58 shows the Mohr's circle based on maximum pore pressure as failure criterion. With the effective cohesion intercept constrained to zero, the envelope gives an effective stress friction angle equal to  $35^\circ$ .

For failure based on maximum principal stress ratio, the Mohr's circle for the sample is shown in Figure 59. An effective stress friction angle of  $38^\circ$  was computed using this failure criterion.

Figure 60 illustrates the Mohr's circle using 10% limiting strain as failure criterion. The value of  $\phi'$  calculated is equal to  $38^\circ$ .

Figure 61 shows the Mohr's circle for failure based on 15% limiting strain. The effective stress friction angle computed is equal to  $38^\circ$ .

For  $A\text{-bar}=0$ , the Mohr's circle is shown in Figure 62. The value of  $\phi'$  calculated using this failure criterion is equal to  $38^\circ$ .

**Figure 58** Effective Stress Mohr's Circle Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample of Cape Canaveral Silt For Failure Based On Maximum Pore Pressure

**Figure 59** Effective Stress Mohr's Circle Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample of Cape Canaveral Silt For Failure Based On Maximum Principal Stress Ratio

**Figure 60** Effective Stress Mohr's Circle Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample of Cape Canaveral Silt For Failure Based On 10% Limiting Strain

**Figure 61** Effective Stress Mohr's Circle Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample of Cape Canaveral Silt For Failure Based On 15% Limiting Strain

**Figure 62** Effective Stress Mohr's Circle Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample of Cape Canaveral Silt For Failure Based On  $A\text{-bar} = 0$

A summary of the effective stress friction angles measured for different failure criteria are given in Table 12. Again, the maximum pore pressure failure criterion gave the lowest value of the effective stress friction angle. For the different failure criteria, except  $\sigma_{dmax}$  and  $u_{max}$ , the values of  $\phi'$  are all equal to  $38^\circ$ . This can be well compared to  $\phi'$  obtained from the effective stress path which gave a value equal to  $38.5^\circ$ .

#### **Total Stress Interpretation of CU Test On Overconsolidated Undisturbed Samples of Cape Canaveral Silt**

The undrained strength ratio of Cape Canaveral silt was calculated in the same manner as the previous silt samples.

Similar to the effective stress interpretation of the test results, maximum deviator stress as failure criterion could not be applied because the sample never exhibited a peak deviator stress throughout the test.

Figure 63 shows the undrained strength and effective consolidation pressure relationship for failure based on maximum pore pressure. The  $S_u/p$  calculated is equal to 0.83.

**Table 12 Values of the Effective Stress Friction Angles  
Determined For Different Failure Criteria For  
CU Test On Cape Canaveral Silt**

| <b>Failure Criteria</b>             | <b><math>\phi'</math><br/>(Degrees)</b> | <b>Average<br/>Strain To<br/>Failure (%)</b> |

**Figure 63 Undrained Shear Strength-Effective Consolidation Pressure Relationship Measured For CU Triaxial Test On Overconsolidated Undisturbed Sample of Cape Canaveral Silt For Based On Maximum Pore Pressure**

Figure 64 illustrates the data for failure based on maximum principal stress ratio. The  $S_u/p$  measured is equal to 1.26.

For failure based on 10% and 15% limiting strains, the relationships between  $S_u$  and  $\sigma_3'_{con}$ , are shown in Figures 65 and 66 respectively. The  $S_u/p$  ratios calculated are 1.34 for 10% limiting strain, and 1.6 for 15% limiting strain.

Figure 67 illustrates the data for failure based on  $A\text{-bar}$  equal to zero. The  $S_u/p$  measured is equal to 1.60.

Table 13 summarizes the  $S_u/p$  ratios determined for the different failure criteria. Maximum pore pressure as failure criterion gave the lowest undrained strength ratio equal to 0.83. The other failure criteria, except  $\sigma_{dmax}$ , gave  $S_u/p$  ratios that range from 1.30 to 1.60.

## **GRAY SILT AND BROWN SILT**

### **West Williamson L.P.P. Pump Station**

Duncan and Sehn (1987) tested silt specimens from a Pumping Station in West Williamson, West Virginia. The silts obtained from the site were named Gray silt and Brown silt. The study conducted by Duncan and Sehn was performed to determine the cause of settlements that occurred at the site which resulted in a culvert failure. The series of triaxial tests were conducted in two phases. The first phase was done in Ohio River Division Laboratory, and the second phase was conducted in the Virginia Tech Geotechnical Laboratory. The longitudinal cross-section of the site is shown in Figure 68.

### **Index Properties of Gray Silt And Brown Silt, West Williamson L.P.P. Pump Station**

The plasticity, water content, and consistency of brown silt and gray silt are summarized in Table 14 and 15 for Phase I and Phase II, respectively. It can be seen that the properties of the silts obtained from both phases are similar. The plasticity charts for the specimens are shown in Figures 69 and 70. Most of the

Figure 69 Plasticity Chart For Gray Silt

Figure 70 Plasticity Chart For Brown Silt

samples obtained from the site are classified as ML based on the Unified Classification System. The natural soil deposit comprises of dark brown sandy silt with low to medium plasticity underlain by low plasticity gray to dark gray silt. The average specific gravity for the gray silt is 2.67 and 2.70 for the brown silt. The gradation curves are shown in Figures 71, 72, and 73 and the grain size components are summarized in Table 16. Consolidation tests results for gray silt and brown silt are shown in Figures 74 and 75 respectively.

#### **Consolidated Undrained Triaxial Tests On Overconsolidated Undisturbed Samples of Gray Silt**

CU Triaxial tests were conducted on three samples of gray silt. The specimens were obtained from boring number UD-85-2 at depths of 23 feet to 25.2 feet. Table 17 gives the initial properties of gray silt for CU triaxial tests and the Atterberg limits are given in Table 18. Normal procedures of back pressure saturation were done on the samples to insure that they were fully saturated before shearing. Based on the consolidation curve shown in Figure 74, the past consolidation pressure for gray

Figure 74 Consolidation Test On Gray Silt, West Williamson L.P.P. Pump Station (Duncan and Sehn, 1985)

Figure 75 Consolidation Test Results For Brown Silt  
West Williamson L.P.P. Pumping Plant  
(Duncan and Sehn, 1985)

silt ranges from 35 psi to 42 psi determined by the Casagrande method. The effective consolidation pressure applied during the CU tests are 4.9 psi, 10.6 psi, and 21.0 psi. These effective consolidation pressures correspond to overconsolidation ratios of 7.8, 3.6, and 1.8.

Shown in Figure 76 are the stress-strain diagrams for the samples. All samples showed a peak in stress-strain curve. The sample consolidated to the highest  $\sigma_3'_{con}$ , 21 psi, had a very pronounced peak at strain of about 8%. The samples consolidated at 4.9 psi and 10.6 psi reached their maximum deviator stresses at strains of approximately 14% and 18%, respectively.

Shown in Figures 77 and 78 are the minor effective stress-strain and principal stress ratio-strain relationships. The average principal stress ratio calculated from the tests is 4.40 at an average strain of 5.5%.

Figures 79 and 80 illustrate the A-bar-strain and pore pressure-strain relationships. Pore pressures reached their maximum values at strains ranging from 0.5% to 5.2% in the order of increasing consolidation pressures. For the sample consolidated to the highest consolidation pressure, the pore pressure behaved differently compared with the other two samples. After

**Figure 78** Principal Stress Ratio-Strain Relationship Measured For CU Triaxial Tests On Overconsolidated Undisturbed Samples Of Gray Silt, West Williamson L.P.P. Pump Station (Ud-85-2-7B)

**Figure 79 A-bar-Strain Relationship Measured For CU Triaxial Tests On Overconsolidated Undisturbed Samples Of Gray Silt, West Williamson L.P.P. Pump Station (Ud-85-2-7B)**

**Figure 80** Pore Pressure-Strain Relationship Measured For CU Triaxial Tests On Overconsolidated Undisturbed Samples Of Gray Silt, West Williamson L.P.P. Pump Station (Ud-85-2-7B)

reaching a maximum value at 5% strain, it decreased to about 10.4 psi at 11.5% strain, and then increased to a value of about 12.5 psi at 20% strain. The behavior of the pore pressure for this sample is reflected in the effective stress paths shown in Figure 81. The point where the pore pressure started to increase, the effective stress path started to reverse direction where both  $p'$  and  $q$  decreased. Based on the stress paths measured for these tests, one unique  $K_f$  line cannot be fitted because of scatter in the results. Plotting the  $K_f$  line for each stress path would give values of  $\alpha$  equal to  $32^\circ$ ,  $33^\circ$ , and  $34^\circ$ . These give an average value of  $\alpha$  equal to  $33^\circ$  which corresponds to an effective stress friction angle,  $\phi'$ , equal to  $40^\circ$ .

#### **Effective Stress Interpretation of CU Tests On Overconsolidated Undisturbed Samples of Gray Silt**

All failure criteria could be applied to the CU tests results on gray silt, except that based on  $A\text{-bar} = 0$ .

Shown in Figure 82 are the Mohr's circles for the samples based on maximum pore pressure. Constraining the effective cohesion intercept to zero, the effective

**Figure 81** Effective Stress Paths Measured For CU Triaxial Tests On Overconsolidated Undisturbed Samples Of Gray Silt, West Williamson L.P.P. Pump Station (Ud-85-2-7B)

**Figure 82** Effective Stress Mohr's Circles Measured For CU Triaxial Tests On Overconsolidated Undisturbed Gray Silt For Failure Based On Maximum Pore Pressure (UD-101-S1-A)

stress friction angle measured is  $34^\circ$ . This represents the best estimate due to scatter in the results.

The Mohr's circles based on maximum deviator stress are plotted in Figure 83. The effective stress friction angle computed is  $38^\circ$ .

Figure 84 shows the Mohr's circles based on maximum principal stress ratio. The effective stress friction angle computed is equal to  $38^\circ$ . This also represents the best estimate due to some scatter in the results.

Shown in Figures 85 and 86 are the Mohr's circles using 10% and 15% limiting strains as failure criteria. Constraining the effective cohesion intercept to zero, the envelopes give values of effective friction angle equal to  $37^\circ$  for both 10% and 15% limiting strains.

Only one sample is represented for the envelope drawn based on  $A\text{-bar} = 0$ . The Mohr's circle for this failure criterion is shown in Figure 87. The computed effective stress friction angle is  $37^\circ$ .

The values of the effective stress friction angles based on different failure criteria are summarized in Table 19. The lowest effective stress friction angle was derived from the maximum pore pressure as a failure criterion and the other failure criteria gave values that range from  $37^\circ$  to  $38^\circ$ .

**Total Stress Interpretation of CU Triaxial Tests On Overconsolidated Undisturbed Samples of Gray Silt.**

Using the CU triaxial tests on overconsolidated samples of undisturbed gray silt, the undrained strength ratios can be evaluated using different failure criteria.

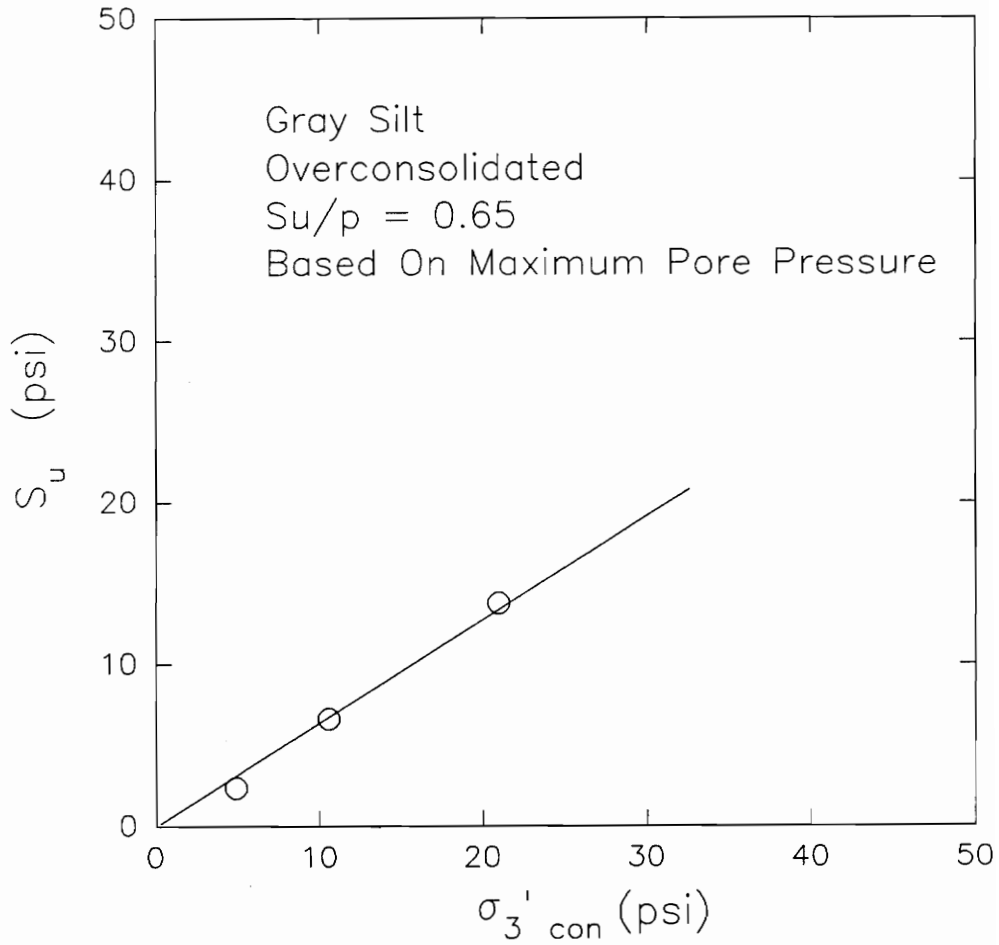

Shown in Figure 88 is the relationship between undrained shear strength and effective consolidation pressure for failure based on maximum pore pressure. An  $S_u/p$  of 0.65 was calculated from this failure criterion.

Figure 89 shows the undrained strength ratio based on maximum deviator stress. It can be seen that for varying degrees of consolidation, the  $S_u/p$  ratio is not constant.

For failure based on maximum principal stress ratio, the value of the undrained strength ratio is shown in Figure 90. The calculated value of  $S_u/p$  is 0.80.

Using 10% and 15% limiting strains as failure criteria, as shown in Figures 91 and 92, calculation of  $S_u/p$  ratio using the previous method is not possible because of the non-linear relationship between undrained strength and effective consolidation pressure.

Figure 93 shows the value of  $S_u/p$  based on  $A\text{-bar} = 0$  as failure criterion. An  $S_u/p$  of 1.5 was calculated based

on this failure criterion. This does not represent a reliable estimate since it is a representative of only one sample.

Table 20 summarizes the values of  $S_u/p$  determined for different failure criteria for gray silt. As with the previous effective stress analysis, the lowest value of the undrained strength ratio was obtained from failure based on maximum pore pressure. Skempton's correlation of  $S_u/p$  with plasticity index cannot be applied to these tests results because the samples were overconsolidated.

**Table 20  $S_u/p$  Ratios Determined For Different Failure Criteria for CU Test On Gray Silt**

| <b>Failure Criteria</b>     | <b><math>S_u/p</math></b> | <b>Average Strain To Failure (%)</b> |
|-----------------------------|---------------------------|--------------------------------------|

**Unconsolidated Undrained Tests On Overconsolidated Undisturbed Samples of Gray Silt, West Williamson L.P.P. Pumping Plant**

Six UU triaxial tests were performed on different samples of gray silt. Four UU triaxial tests were conducted on sample UD-101-S2-A, one on sample UD-100-S4-A1, and one on sample UD-101-S2-C2. The plots for sample UD-101-S2-A are shown in Figures 94, 95, 96, and 97. For the other gray silt samples, the results are shown in Appendix A.

The properties for UU triaxial tests of sample UD-101-S2-A are given in Table 21. The cell pressures used during the tests were 4.9 psi, 20.8 psi, 10.4 psi, and 34.7 psi. Shown in Figure 94 are the deviator stress-strain relationships. It can be seen that the stress-strain curves are independent of cell pressures, indicating that the samples have similar properties and were saturated prior to shearing. The stress-strain curve of the sample subjected to a cell pressure of 34.7 psi had a peak deviator stress at a strain of about 12%. The other three samples did not show any peak behavior in their stress-strain relationship.

Figure 95 illustrates the Mohr's circles based on maximum deviator stress as failure criterion. Using  $\phi_u=0$

interpretation, the undrained shear strength,  $S_u$ , computed is 8.30 psi. Using an effective overburden pressure of 21 psi, the  $S_u/p$  ratio would be 0.40.

Shown in Figure 96 are the Mohr's circles using 10% limiting strain failure criterion. The undrained strength,  $S_u$ , calculated is 8.70 psi, which gives an undrained strength ratio,  $S_u/p$ , of 0.41.

The Mohr's circles based on 15% limiting strain are shown in Figure 97. The undrained strength calculated is 8.8 psi. This gives an undrained strength ratio,  $S_u/p$ , equal to 0.42.

Table 22 summarizes the values of  $S_u/p$  for different failure criteria for sample UD-101-S2-A. The values of  $S_u/p$  based on different failure criteria have an average value equal to 0.41.

The plots measured for samples UD-100-S4-A1 and UD-101-S2-C2 are shown in Appendix A. Tables 23 and 24 summarize the values of  $S_u/p$  for these samples for different failure criteria.

## Unconsolidated Undrained Triaxial Tests On Overconsolidated Undisturbed Samples of Brown Silt

Eight UU triaxial tests were conducted on Brown silt at the Virginia Tech Laboratory and ten UU triaxial tests were conducted at ORD Laboratory. Results of UU tests for sample UD-85-4-9 are shown in Figures 98, 99, 100, and 101. The results of UU tests for the other samples of brown silt are shown in Appendix B.

For sample UD-85-4-9, four UU triaxial tests were performed. The properties of the specimens are given in Tables 25 and 26.

Figure 98 shows the deviator stress-strain relationship for the samples. All specimens exhibited similar behavior, wherein the deviator stress increased rapidly at small strains and showed a distinct break at a strain of about 1%. The deviator stress continued to increase with increasing strain, but did not show any strain softening for the duration of the tests.

Figure 99 shows the Mohr's circles for failure based on maximum deviator stress. Using  $\phi_u=0$  interpretation of the results, the undrained shear strength calculated is equal to 2.2 psi. These samples were obtained at a depth of approximately 21 feet. The effective overburden

**Figure 99** Mohr's Circles Measured For UU Triaxial Tests On Undisturbed Samples of Brown Silt For Failure Based On Maximum Deviator Stress, West Williamson L.P.P. Pumping Plant (Sample UD-85-4-9)

pressure at this depth is approximately 18 psi. For the failure criteria based on maximum deviator stress, the calculated  $S_u/p$  is equal to 0.12.

The Mohr's circles based on 10% limiting strain as failure criterion are shown in Figure 100. A small scatter in the results can be attributed to disturbance effects. The undrained shear strength,  $S_u$ , calculated from these results is 2.6 psi which gives an undrained strength ratio equal to 0.15.

Shown in Figure 101 are the Mohr's circles for failure based on 15% limiting strain. The best estimate of the undrained shear strength is 3.1 psi which gives a value of  $S_u/p$  equal to 0.17.

Table 27 summarizes the values of  $S_u/p$  for UU triaxial tests on Sample UD-85-4-9 for different failure criteria. The  $S_u/p$  ratios calculated would give an average value equal to 0.13.

The plots measured for UU triaxial tests on the other samples of Brown silt are shown in Appendix B. A summary of the values of undrained strength ratios for different failure criteria are given in Tables 28 and 29.

## **RHODE ISLAND SILT**

Samples of remolded Rhode Island silt were tested by Nacci and D'Andrea (1976). Obtaining undisturbed samples by conventional sampling techniques, including thin-walled cylinder and block sampling, was not possible because the liquidity index of this silt was above 1.00. The silt liquefies at small amounts of disturbance and furthermore, it was assumed that the specimen densified during transit. To duplicate the natural fabric composition of the soil for laboratory testing, a unique sample preparation technique was devised as shown in Figure 102. Bulk samples were obtained from the site and these were mixed with distilled water to produce a slurry. Cylindrical triaxial specimens were obtained by slow sedimentation of this slurry. During sample preparation, the silt was consolidated under a pressure of approximately 7.10 psi.

### **Index Properties of Rhode Island Silt**

Rhode Island Silt is a loose layered silt. The gradation curve for this silt is shown in Figure 103 and the grain size components are given in Table 30. The gradation curve shows that the sample consisted mostly of

Figure 102 Sedimentation Apparatus For Rhode Island Silt

| % Silt            | 87%           |
| % Clay            | 3%            |

silt particles with grain size diameter less than 0.074 mm and greater than 0.002 mm. The Atterberg limits are plotted on the plasticity chart in Figure 104 and summarized in Table 31. The sample plots just below the A-line. Rhode Island silt has specific gravity of 2.75, and has a high natural water content, ranging from 30% to 40%.

#### **Consolidated Undrained Triaxial Test On Remolded Rhode Island Silt**

CU Triaxial tests were conducted on remolded specimens of normally consolidated Rhode Island Silt using Geonor equipment. Conventional procedures of back pressure saturation were conducted prior to consolidation to give full saturation on the specimen. The specimen was sheared under a strain rate of 3 percent per hour. The slow rate of shearing the sample insured that the pore pressure measured at the base of the sample was the same pore pressure throughout the sample. Figure 105 shows the stress-strain curve for the specimen. A maximum deviator stress was not attained for the range of strains used. Shown in Figures 106 and 107 are the effective stress-strain and principal stress ratio-strain relationships. No peak behavior can be seen on the principal stress

Measured For CU Triaxial Test On Normally  
Consolidated Rhode Island Silt**

ratio-strain relationship. Figure 108 shows that the maximum pore pressure occurred at less than 3 percent strain. The same behavior can be seen from the  $\bar{A}$ -Strain relationship because of direct proportionality between  $\bar{A}$  and pore pressure, as shown in Figure 109.

#### **Effective Stress Interpretation of CU Triaxial Test On Remolded Rhode Island Silt**

The results clearly indicate that the maximum pore pressure is the only failure criteria that can be applied. The effective stress Mohr's circle is shown in Figure 110 which renders an effective stress friction angle equal to  $27^\circ$ . The envelope was determined by constraining the cohesion intercept  $c'$  to zero. Figure 111 shows the effective stress path for the Rhode Island silt. The  $K_f$  line defined gives a value of  $\alpha$  equal to  $25^\circ$ . This corresponds to an effective friction angle equal to  $28^\circ$ .

**Figure 111 Effective Stress Path Measured For CU Triaxial Test On Normally Consolidated Rhode Island Silt**

### Total Stress Interpretation of CU Test On Remolded Rhode Island Silt

Undrained shear strength can also be determined using the consolidated undrained triaxial test. This is done by determining the relationship between the undrained shear strength,  $S_u$ , measured during the test and the effective consolidation pressure,  $\sigma_3'_{con}$ . For normally consolidated clays, the undrained strength ratio,  $S_u/p$ , is constant.

Shown in Figure 112 is the relationship between the undrained strength and effective consolidation pressure for the Rhode Island silt. This is based on maximum pore pressure. No other data can be compared to this relationship because there is only one failure criteria satisfied in this test. The slope of the line drawn from the origin through the data point represents the undrained strength ratio. The value of  $S_u/p$  derived from this test is 0.26. This can be compared to Skempton's correlation of  $S_u/p$ . Using a plasticity index equal to 6%, the correlation would give an  $S_u/p$  equal to 0.13.

**Figure 112 Undrained Shear Strength-Effective Consolidation Pressure Relationship Measured For CU Triaxial Test On Normally Consolidated Rhode Island Silt For Failure Based On Maximum Pore Pressure**

## **Yukon Silt**

Hampton (1981) summarized the triaxial tests results performed for Yukon silt. The samples were obtained from the western and central portion of the Yukon Prodelta in Norton Sound, Alaska. The specimens were tested at Cornell University in the summer of 1979.

### **Consolidated Undrained Test On Normally Consolidated Undisturbed Yukon Silt (Western Prodelta)**

Undisturbed samples of Yukon silt obtained from the western prodelta were tested in CU triaxial tests. The effective consolidation pressure used in the test was 42.60 psi. This corresponds to an induced overconsolidation ratio equal to 1.

Figure 113 shows the deviator stress-strain relationship for the specimen. Similar to the previous silt samples, there was a rapid increase in deviator stress at small strains. After a steep portion, the deviator stress continued to increase with strain, following a flatter slope. No peak was observed on the stress-strain diagram. The test was generally terminated at 10% strain or when a failure plane was observed in the sample.

**Figure 113 Deviator Stress-Strain Relationship Measured For CU Triaxial Test On Undisturbed Sample of Normally Consolidated Yukon Silt (Western Prodelta)**

Figures 114 and 115 illustrate the minor effective stress-strain and principal stress ratio-strain relationships. The sample had a maximum principal stress ratio equal to 5.70 at a strain of about 5%.

Shown in Figures 116 and 117 are the  $\bar{A}$ -strain and pore pressure-strain relationships. The pore pressure increased rapidly at small strains and reached a peak at a strain of about 3.5%. Although the pore pressure decreased after reaching a maximum value, it remained positive throughout the test.

The effective stress path for the specimen is shown in Figure 118. The behavior exhibited by the stress path was to approach the  $K_f$  line at low strains and continue to climb the  $K_f$  line as strains increased. An  $\alpha$  equal to  $35^\circ$  was measured, which corresponds to an effective stress friction angle equal to  $44^\circ$ .

#### **Effective Stress Interpretation of The CU Triaxial Test On Normally Consolidated Undisturbed Yukon Silt (Western Prodelta)**

Some of the failure criteria cannot be applied to the test results since the test was terminated at low strains.

Figure 119 illustrates the Mohr's circle for failure based on maximum pore pressure. Constraining the

effective cohesion intercept to zero, the effective stress friction angle calculated is equal to  $41^\circ$ .

A  $\phi'$  equal to  $45^\circ$  was measured based on maximum principal stress ratio. The Mohr's circle for this failure criterion is shown in Figure 120.

Shown in Figure 121 is the Mohr's circle based on 10% limiting strain. The value of the effective stress friction angle measured using this failure criterion is  $45^\circ$ .

A summary of the effective stress friction angles for the different failure criteria is given in Table 32. The value of  $\phi'$  obtained using the different failure criteria applied, except maximum pore pressure, are all equal to  $45^\circ$ . This can be well compared with the  $\phi'$  obtained from the effective stress path which gave a value equal to  $44^\circ$ .

#### **Total Stress Interpretation Of The CU Triaxial Test On Undisturbed Sample of Normally Consolidated Yukon Silt (Western Prodelta)**

The determination of the undrained strength ratio for these test results was done in the same manner as the previous silt samples.

| 15% Limiting Strain             | N/A                                     | N/A                                  |
| A-bar = 0                       | N/A                                     | N/A                                  |

Figure 122 shows the relationship between the undrained shear strength and effective consolidation pressure for failure based on maximum pore pressure. The  $S_u/p$  ratio calculated is equal to 0.63.

Shown in Figure 123 is the determination of  $S_u/p$  based on maximum principal stress ratio. An  $S_u/p$  of 0.74 was measured for this failure criterion.

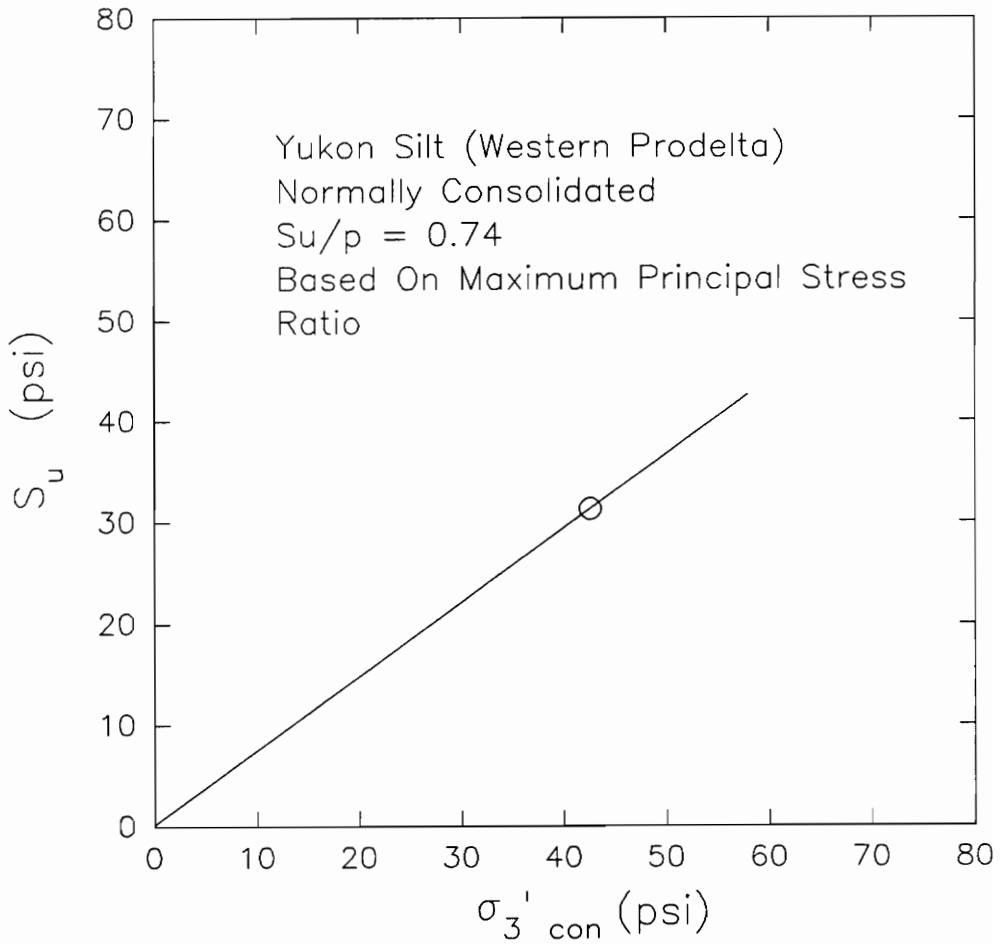

Using 10% limiting strain as failure criterion, the  $S_u/p$  calculated is equal to 1.10. This is shown in Figure 124.

Table 33 summarizes the  $S_u/p$  ratios determined for the different failure criteria. The lowest value of  $S_u/p$  was obtained for failure based on maximum pore pressure.

| A-bar = 0                       | N/A                       | N/A                                  |

**Consolidated Undrained Triaxial Tests On Normally Consolidated Undisturbed Samples of Yukon Silt (Central Prodelta)**

A series of CU triaxial tests were performed on undisturbed samples of Yukon silt. The samples were obtained from central prodelta. The effective consolidation pressures used for the test were 3.3 psi, 5.6 psi, 14.7 psi, 42.3 psi, 44.0 psi, and 50.0 psi.

Shown in Figure 125 are the deviator stress-strain relationships for the samples. Similar to the sample from western prodelta, the stress-strain diagrams had a rapid increase in the deviator stress at small range of strains. Three samples had a peak in the stress-strain diagrams at an average strain of 10%. Because of the dilative tendencies of the other specimens, the deviator stresses continued to increase with increasing strains. Failure did not correspond to peak deviator stress for these samples.

Figure 126 and 127 illustrate the minor effective stress-strain and principal stress ratio-strain relationships. The samples reached an average maximum principal stress ratio equal to 4.6 at an average strain of 5%.

**Figure 125 Deviator Stress-Strain Relationship Measured For CU Triaxial Tests On Undisturbed Samples of Yukon Silt (Central Prodelta)**

**Figure 126** Minor Effective Stress-Strain Relationship Measured For CU Triaxial Tests On Undisturbed Samples of Yukon Silt (Central Prodelta)

**Figure 127 Principal Stress Ratio-Strain Relationship Measured For CU Triaxial Tests On Undisturbed Samples of Yukon Silt (Central Prodelta)**

A-bar-strain and pore pressure strain relationships are shown in Figures 128 and 129. The pore pressures peaked at a strain of about 1%, then decreased continually as strains increased. The samples consolidated to 3.3 psi, 42.3 psi, and 44 psi had positive pore pressures throughout the tests.

Figure 130 shows the effective stress paths for the specimens. The behavior exhibited by the stress paths were to approach the  $K_f$  line at low strains and continued to climb the  $K_f$  as strains increased. The  $K_f$  line defined by the stress paths defines an  $\alpha$  equal to  $32^\circ$ . This corresponds to an effective stress friction angle,  $\phi'$ , equal to  $38^\circ$ .

#### **Effective Stress Interpretation of The CU Triaxial Tests On Normally Consolidated Undisturbed Samples of Yukon Silt (Central Prodelta)**

The test results indicate that not all the different failure criteria could be applied for all the samples. The effective stress interpretation for these samples were done in the same manner as the previous silt samples.

Figure 131 shows the Mohr's circles for failure based on maximum pore pressure. The results show that

**Figure 128 A-bar-Strain Relationship Measured For CU Triaxial Tests On Undisturbed Samples of Yukon Silt (Central Prodelta)**

**Figure 129 Pore Pressure-Strain Relationship Measured For CU Triaxial Tests On Undisturbed Samples of Yukon Silt (Central Prodelta)**

**Figure 130 Effective Stress Paths Measured For CU Triaxial Tests On Undisturbed Samples of Yukon Silt (Central Prodelta)**

**Figure 131 Effective Stress Mohr's Circles Measured For CU Triaxial Tests On Undisturbed Samples of Yukon Silt For Failure Based On Maximum Pore Pressure (Central Prodelta)**

there was scatter in the data. With the effective cohesion intercept constrained to zero, the envelope gave an effective stress friction angle equal to  $31^\circ$ .

Figure 132 illustrates the Mohr's circles based on maximum deviator stress as failure criterion. The effective stress friction angle calculated is equal to  $36^\circ$ .

The Mohr's circles based on maximum principal stress ratio are shown in Figure 133. There was little scatter in the data. The effective stress friction angle measured for this failure criterion is equal to  $37^\circ$ .

Figures 134 and 135 illustrate the Mohr's circles using 10% and 15% limiting strains. A  $\phi'$  equal to  $35^\circ$  was measured for both failure criteria.

An effective stress friction angle equal to  $37^\circ$  was measured using  $A\text{-bar}$  as failure criterion. The Mohr's circles are shown in Figure 136.

A summary of the effective stress friction angles for the different failure criteria is given in Table 34. Similar to the other silt samples, the lowest value of  $\phi'$  was measured using maximum pore pressure as failure criterion. The  $\phi'$  calculated from the other failure criteria ranged from  $35^\circ$  to  $37^\circ$ , which can be compared to a  $\phi'$  equal to  $38^\circ$  obtained from the effective stress path.

| $\bar{A} = 0$                  | 37                                      | 6%                                           |

**Total Stress Interpretation of The CU Triaxial Tests On Normally Consolidated Samples of Yukon Silt (Central Prodelta)**

The undrained strength ratios for these samples were determined in the same way as the sample obtained from western prodelta. Similar to the effective stress interpretation, not all the failure criteria could be applied to all the samples.

Figure 137 shows the relationships between the undrained shear strength and effective consolidation pressure for failure based on maximum pore pressure. The  $S_u/p$  calculated is equal to 0.6.

An  $S_u/p$  equal to 2.7 was calculated using the maximum deviator stress as failure criterion. The data are plotted in Figure 138.

Shown in Figure 139 is the determination of  $S_u/p$  using the maximum principal stress ratio. The  $S_u/p$  measured for this failure criterion is equal to 1.5.

The data for failure based on 10% limiting strain are shown in Figure 140. The  $S_u/p$  ratio calculated is equal to 1.7.

Figure 141 illustrates the determination of the undrained strength ratio based on 15% limiting strain. An

$S_u/p$  equal to 1.9 was calculated using this failure criterion.

The data for failure based on  $A\text{-bar}=0$  are plotted in Figure 142. The value of  $S_u/p$  is equal to 1.5.

Table 35 summarizes the  $S_u/p$  ratios for the different failure criteria. The lowest undrained strength ratio was determined using maximum pore pressure as failure criterion.

## CHAPTER 5

### ANALYSIS OF TEST RESULTS

#### Effects of Failure Criteria On The Values of The Effective Stress Friction Angles

Six different failure criteria were applied to the test results to evaluate the values of the effective stress friction angles. The results indicate that the choice of failure criteria influenced the values of  $\phi'$ .

Defining failure based on maximum pore pressure, the  $\phi'$  measured were much lower than determined using the other methods. Figure 143 illustrates the comparison of the effective stress friction angles measured for failure based on maximum pore pressure and maximum principal stress ratio. It can be seen that there is considerable amount of variation in the values of  $\phi'$ . A difference as high as  $6^\circ$  can be measured from the two failure criteria.

The values of  $\phi'$  measured from the different failure criteria, except  $u_{\max}$ , showed small variations. Figure 144 illustrates the comparison of the  $\phi'$  measured using maximum principal stress ratio and 10% limiting strain as failure criteria. The results indicate that the values of  $\phi'$  are fairly consistent. A variation of  $\pm 1^\circ$  could be measured from the two failure criteria, which could be attributed to scatter in the test results.

**Figure 143 Comparison of the Effective Stress Friction Angles Measured For The Different Silt Samples For Failure Based On Maximum Principal Stress Ratio and Maximum Pore Pressure**

**Figure 144 Comparison of the Effective Stress Friction Angles Measured For The Different Silt Samples For Failure Based On Maximum Principal Stress Ratio and 10% Limiting Strain**

The conservative values of  $\phi'$  based on maximum pore pressure could be explained by the dilative behavior of the specimens. The pore pressures during the tests increased only temporarily at small strains, then dropped as strains increased. The decrease in pore pressures increased the effective stresses, thus making the sample stronger at higher strains. This criteria also produced the smallest strains to failure. The maximum pore pressures were reached at strains ranging from 1% to 4%.

The consistency in the values of  $\phi'$  using the different failure criteria, except  $u_{\max}'$ , could also be explained by the dilative behavior of the samples. The general trends of the effective stress paths were to approach the  $K_f$  line at small strains, then continued to climb the  $K_f$  line as strains increased. For soils with the effective cohesion intercept equal to zero, the maximum principal stress ratio corresponds closely to the condition where the stress path reached the  $K_f$  line. As shown in Table 36, the average strains to failure for maximum principal stress ratio were less than the average strains to failure for the other failure criteria. Since all the referenced silts behaved as  $c'=0$  materials, then the  $p'$ - $q$  coordinates of the different failure criteria, except  $u_{\max}'$ , are plotted on the  $K_f$  line. For this

**Table 36 Average Strains To Failure Measured For CU Triaxial Tests For The Different Failure Criteria**

| <b>Failure Criteria</b> | <b><math>u_{max}</math></b> | <b><math>\sigma_{dmax}</math></b> | <b><math>\sigma_1'/\sigma_3'</math></b> | <b>10%</b> | <b>15%</b> | <b>A=0</b> |

| Yukon Silt              |                             |                                   |                                         |            |            |            |
| Western Prodelta (CU)   | 3.5%                        | N/A                               | 5%                                      | 10%        | N/A        | N/A        |
| Central Prodelta (CU)   | 1%                          | 10%                               | 5%                                      | 10%        | 15%        | 6%         |

condition, the effective stress friction angle would be independent from the type of failure criteria.

These analyses can be well illustrated by the test results from Cape Canaveral silt. Figure 145 illustrates the effective stress path for the sample showing the points corresponding to the different failure criteria. The point represented by  $u_{\max}$  was not yet on the  $K_f$  line, which is why the value of  $\phi'$  calculated was  $3^\circ$  below the  $\phi'$  measured from the other failure criteria. All other failure points are located on the  $K_f$  line.

**Figure 145 Effective Stress Path Measured For CU Triaxial Test On Cape Canaveral Silt**

## Effects of Failure Criteria On The Values of The Undrained Strength Ratios

Undrained shear strengths were evaluated using the CU and UU triaxial test results for the different silt samples. Due to the dilatant nature of the silt samples, a unique undrained shear strength could not be obtained. Six different failure criteria were used to determine the values of the undrained strength parameters, and comparisons were made using the undrained strength ratio,  $S_u/p$ . A summary of  $S_u/p$  ratios measured for the different specimens is given in Table 37.

For the normally consolidated Alaskan silt, the results from the CU and UU triaxial tests on the samples were used to evaluate the undrained strength ratios. Interpreting  $S_u/p$  from UU triaxial tests resulted to lower values of  $S_u/p$  as compared to the CU test results. From the CU triaxial tests, the undrained strength ratio calculated using maximum pore pressure was lower than the  $S_u/p$  ratios derived from the other failure criteria. For failure based on  $\sigma_{dmax}$ , the undrained strength ratio calculated was higher than the  $S_u/p$  for the other failure criteria because the average strain to failure for  $\sigma_{dmax}$  was greater than 15%. For normally consolidated clays, Skempton provided a correlation of  $S_u/p$  with the

**Table 37 Values of  $S_u/p$  Ratios From CU And UU Triaxial Tests For  
The Different Failure Criteria**

| Failure Criteria         | $u_{max}$ | $\sigma_{max}$ | $\sigma_1'/\sigma_3'$ | 10%  | 15%  | A=0 |

plasticity index. Test results indicate that using Skempton's equation, the  $S_u/p$  calculated for the Alaskan silt was lower than measured.

The CU triaxial test results for Braehead silt showed scatter in the values of  $S_u/p$ . The lowest value of the undrained strength ratio was measured for failure based on maximum pore pressure. Since the sample failed at a strain of about 28%,  $\sigma_{dmax}$  gave the highest value of  $S_u/p$ , almost four times higher than the average value derived from other failure criteria. Although the sample was normally consolidated, Skempton's equation could not be applied to this specimen because the specimen was non-plastic.

The series of UU and CU triaxial tests for the overconsolidated brown silt and gray silt were used to evaluate the values of  $S_u/p$ . A considerable amount of scatter could be observed from the undrained strength ratios obtained from the UU triaxial tests. The CU tests gave higher values of  $S_u/p$  ratios than UU tests for all failure criteria. Based on the CU triaxial tests on gray silt, the  $S_u/p$  ratio obtained from  $u_{max}$  was lower than the values of  $S_u/p$  calculated from the other failure criteria. Interpretation based on  $\sigma_{dmax}'$ , 10%, and 15% limiting strains were not applied because of the non-linear relationship between  $S_u$  and  $\sigma_3'_{con}$ . Similar to the

previous silt samples, there was difficulty in selecting a unique value of undrained shear strength because of the dilative behavior of the specimens.  $S_u/p$  was greatest for the failure criteria having the largest strain to failure.

For the overconsolidated Cape Canaveral silt, evaluating  $S_u/p$  ratio using  $\sigma_{dmax}$  was not possible because the sample did not show a peak deviator stress throughout the duration of the test. The lowest undrained shear strength was computed from  $u_{max}$  as failure criterion, which was almost half of the mean  $S_u/p$  determined from the other failure criteria. The results indicate that the values of  $S_u/p$  ratios increased with strain which made it difficult to define a unique undrained shear strength for the specimen.

The only failure criteria satisfied for the CU test on the normally consolidated Rhode Island silt was maximum pore pressure. Skempton's correlation of  $S_u/p$  with PI again leads to a conservative value of the undrained strength ratio.

The undrained strength ratios for the Yukon silt were evaluated using the CU triaxial test results on the samples. Due to the dilative behavior of the specimens, the values of  $S_u/p$  ratios increased with strain. Similar

to the other silt samples, maximum pore pressure as failure criterion gave the lowest value of  $S_u/p$ .

The test results from the different silt samples indicate that a unique undrained shear strength for a given silt sample could not be evaluated directly from both UU and CU triaxial tests. The choice of failure criteria influenced the values of the undrained strength ratios measured in CU triaxial tests. Because of the dilatant nature of the silt specimens, the strength increases with strain during shear.

UU triaxial tests resulted in lower values of  $S_u/p$  compared to CU tests results. The difference in the undrained strength parameters may be attributed to disturbance during sampling. Fleming (1985) conducted a study on the effect of disturbance on strengths of silt samples measured in the laboratory. The test results showed that the disturbance decreased the undisturbed strength of Alaskan silt by as much as 42%.

Skempton (1953) presented empirical correlations of undrained shear strength with Atterberg limits. Although the correlation proved to be useful for normally consolidated clays, the application to silts resulted in conservative values of  $S_u/p$ .

A more reliable method of evaluating undrained shear strength parameters is to determine how the undrained

shear strength is related to the changes in pore pressures (Torrey, 1982). The general trend of the stress paths is to approach the  $K_f$  line at small strains, then continue to climb the  $K_f$  line as strains increased.

Figure 146 shows a typical effective stress path for a dilative soil whose effective cohesion intercept is equal to zero. For a point on the stress path that is on the  $K_f$  line, the change in pore pressure and the applied deviator stress could be related to the  $\alpha$ -angle of the  $K_f$  line, expressed as

$$\tan \alpha = \frac{\sigma_d/2}{\sigma_3' \text{ con} + \sigma_d/2 - \Delta u} \quad (4)$$

Simplifying Eq.(4), it can be shown that

$$\frac{2\sigma_3' \text{ con}}{\sigma_d} = \frac{1 - \tan \alpha}{\tan \alpha} - \frac{2\Delta u}{\sigma_d} \quad (5)$$

Since  $\tan \alpha = \sin \phi'$ ,  $S_u/p = \sigma_d/2\sigma_3' \text{ con}$ , and  $A = \Delta u/\sigma_d$ ,

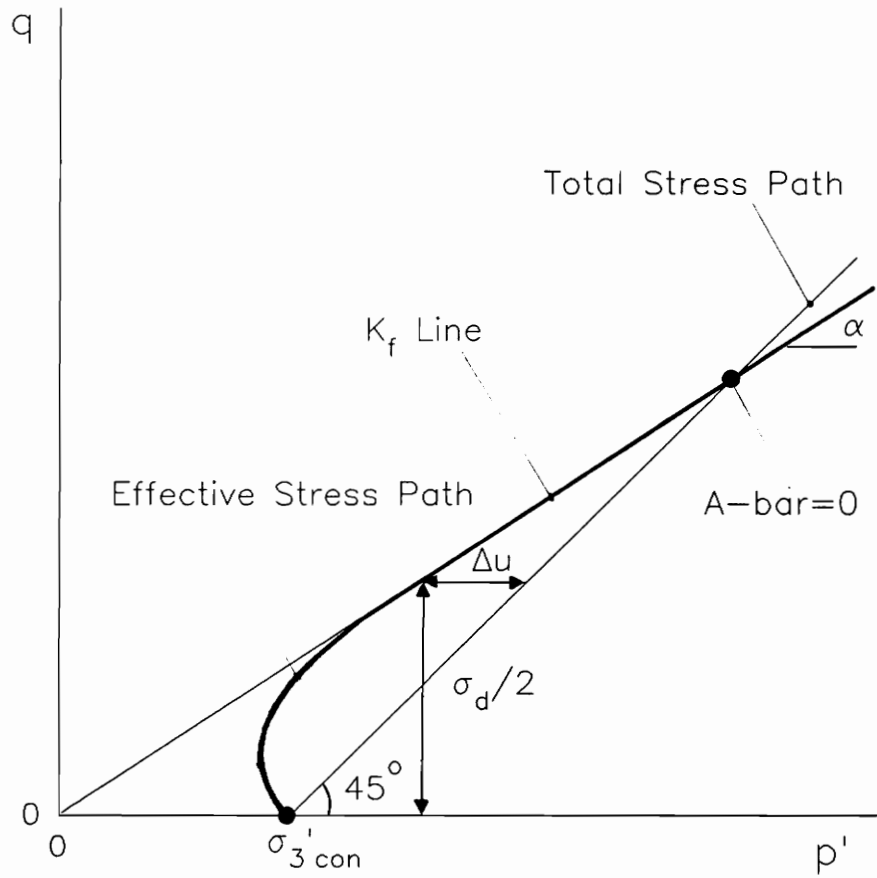

Figure 146 Typical Effective and Total Stress Paths For A Dilative Soil

Eq. (5) could be expressed as

$$S_u/p = \frac{\sin \phi'}{1 - (1 - 2A) \sin \phi'} \quad (6)$$

Using Eq.(6) to evaluate the undrained shear strength parameters will reduce the scatter in the values of the undrained strength ratios because  $\phi'$  could be defined well from the CU triaxial tests. Using the relationship between A-bar and strain, a value of A-bar could be selected in such a way that the shear strength does not correspond to a large amount of strain.

### Possibility of Cavitation In UU Triaxial Tests

In UU triaxial tests on saturated soils, the angle of shearing resistance should be approximately equal to zero. However, when tests are conducted on dilative silts, a deviation from the  $\phi = 0$  condition may occur in UU triaxial tests.

Brandon et al. (1990) presented a plot to determine the limiting undrained shear strength for soils that cavitate (Figure 1). If a silt sample cavitates in UU triaxial tests, the undrained shear strength for a given cell pressure should plot approximately on the contour defined by the effective stress friction angle.

Four samples of the Alaskan silt were tested in UU triaxial tests. All samples were saturated prior to shearing. The representative effective stress friction angle for these samples is equal to  $38^\circ$ . As shown in Figure 147, the undrained shear strengths plot well below the contour lines for the different values of  $\phi'$ . Therefore, cavitation did not occur during the tests.

The values of the undrained shear strengths for sample UD-84-4-9 of brown silt are plotted in Figure 148. The effective stress friction angle for brown silt samples was not measured. Although the value of  $\phi'$  for these samples is not known, it can be assumed that

**Figure 147 Undrained Shear Strengths Measured For UU Triaxial Tests On Alaskan Silt**

**Figure 148 Undrained Shear Strengths Measured For UU Triaxial Tests On Brown Silt, West Williamson L.P.P. Pump Station (Sample UD-85-4-9)**

cavitation did not influence their undrained shear strength because the data plot well beneath the contour lines.

Figures 149 and 150 show the data for samples UD-85-4-11B and UD-100-S1-A for brown silt. Similar to the previous sample, the plots indicate that cavitation did not affect the values of the undrained shear strengths.

For the gray silt samples, the effective stress friction angle measured from the CU triaxial tests is equal to  $38^\circ$ . The undrained shear strengths for samples UD-101-S2-A, UD-100-S4-A1, and UD-100-S2-C2 are plotted in Figures 151, 152, and 153. Since the data plot far below the contour line defined by the effective stress friction angle, it can be inferred that cavitation did not occur during the UU triaxial tests on the samples.

The occurrence of cavitation in UU triaxial tests could also be determined by calculating the value of the pore pressure at failure,  $u_f$ . A sample is said to have cavitated if the value of  $u_f$  decreased to -14.7 psi.

Shown in Figure 154 are the effective and total stress Mohr's circles for a triaxial test. The pore pressure at failure is defined as the difference between the maximum total stresses and maximum effective stresses, expressed as

**Figure 149 Undrained Shear Strength Measured For UU Triaxial Tests On Brown Silt, West Williamson L.P.P. Pump Station (Sample UD-85-4-11B)**

**Figure 150 Undrained Shear Strength Measured For UU Triaxial Tests On Brown Silt, West Williamson L.P.P. Pump Station (Sample UD-100-S1-A)**

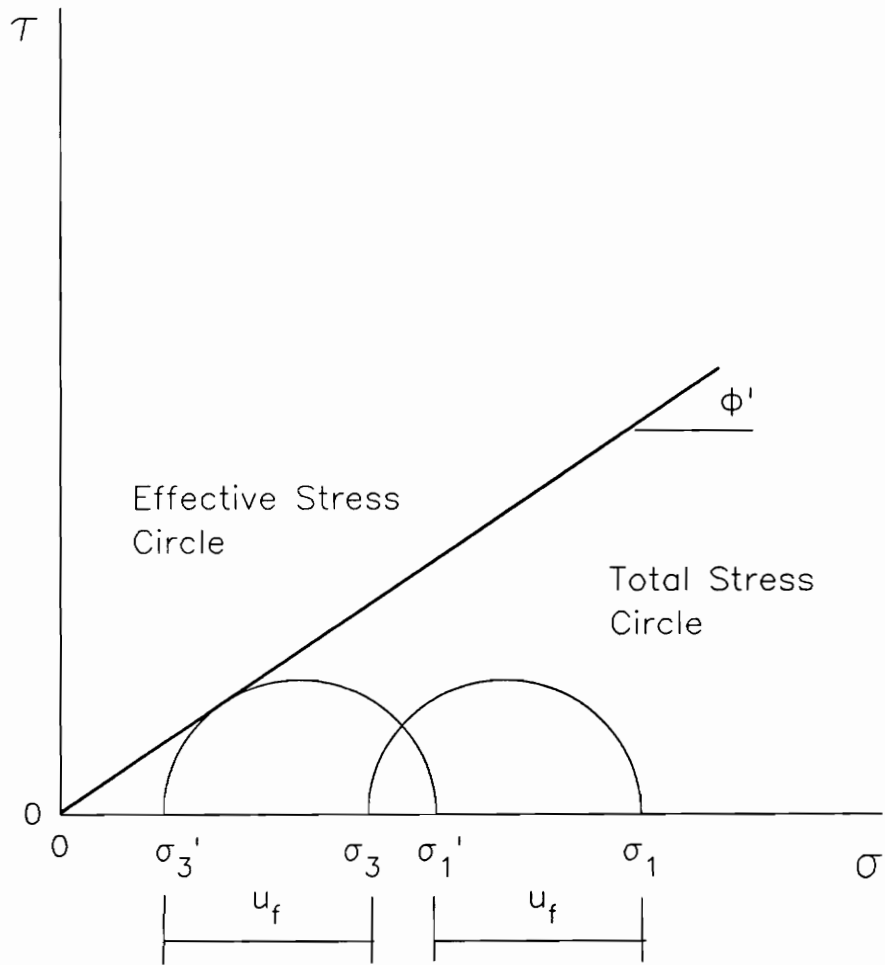

**Figure 151 Undrained Shear Strength Measured For UU Triaxial Tests On Gray Silt, West Williamson L.P.P. Pump Station (Sample UD-101-S2-A)**

**Figure 152 Undrained Shear Strength Measured For UU Triaxial Tests On Gray Silt, West Williamson L.P.P. Pump Station (Sample UD-100-S4-A1)**

**Figure 153 Undrained Shear Strength Measured For UU Triaxial Tests On Gray Silt, West Williamson L.P.P. Pump Station (Sample UD-100-S2-C2)**

**Figure 154 Effective Stress and Total Stress Mohr's Circles For A Triaxial Test**

$$u_f = \sigma_1 - \sigma_1' \quad (7)$$

$$u_f = \sigma_3 - \sigma_3' \quad (8).$$

Considering the effective stress Mohr's circle, the relationship between the maximum effective stresses could be expressed by the equation

$$\sigma_1' = \sigma_3' [\tan^2(45^\circ + \phi'/2)] \quad (9).$$

If Eq.(7) and Eq.(8) are substituted for Eq.(9), the pore pressure at failure could be expressed in terms of the maximum total stresses and effective stress friction angle by the equation

$$u_f = \frac{\sigma_1 - \sigma_3 [\tan^2(45^\circ + \phi'/2)]}{1 - \tan^2(45^\circ + \phi'/2)} \quad (10).$$

Knowing the value of  $\phi'$  from the CU triaxial tests, and the values of the maximum total stresses from UU triaxial tests, the occurrence of cavitation in UU tests can be checked by using Eq. (10).

Table 38 summarizes the pore pressures at failure for the UU triaxial tests on the different silt samples.

Based on the test results, it can be inferred that cavitation did not influence the values of the undrained shear strengths because the values of  $u_f$  calculated were all greater than -14.7 psi.

**Table 38 Values of  $u_f$  Measured for The Unconsolidated Undrained Triaxial Tests On Different Silt Samples**

| Soil Sample  | Cell Pressure<br>(psi) | $u_f$<br>(psi) |
|--------------|------------------------|----------------|
| Alaskan silt | 7.1                    | 4.9            |
| Alaskan silt | 14.2                   | 11.8           |
| Alaskan silt | 21.3                   | 19.1           |
| Alaskan silt | 28.4                   | 26.2           |
| Gray silt    |                        |                |
| UD-101-S2-A  | 4.8                    | -0.3           |
| UD-101-S2-A  | 20.8                   | 15.6           |
| UD-101-S2-A  | 10.4                   | 4.4            |
| UD-101-S4-A1 | 20.8                   | 18.8           |

## CHAPTER 6

### SUMMARY AND CONCLUSIONS

In the course of this research study, the results of tests conducted on different silt samples were investigated to determine the primary factors that control the strength parameters of silts. The silt samples investigated were:

1. Alaskan silt
2. Braehead silt
3. Brown and gray silt from West Virginia
4. Cape Canaveral silt
5. Rhode Island silt
6. Yukon silt

The effective stress friction angles were evaluated using the results from the CU triaxial tests. The UU triaxial test results were used to evaluate the undrained shear strengths of the specimens, and comparisons were made using the undrained strength ratio,  $S_u/p$ .

The results indicate that it is difficult to define failure for both UU and CU triaxial tests. Because of the dilatant nature of the specimens, the strength of the samples keeps increasing during shear. For this reason,

different failure criteria were utilized to evaluate the effective stress friction angles and the undrained shear strengths of the samples. These failure criteria were:

1. Maximum pore pressure
2. Maximum deviator stress
3. Maximum principal stress ratio
4. 10% limiting strain
5. 15% limiting strain
6.  $\bar{A} = 0$
7. Reaching the  $K_f$  line

For CU triaxial tests, the choice of failure criteria influenced the values of the effective stress friction angles. Maximum pore pressure as failure criterion gave the lowest value of the effective stress friction angle. Using the different failure criteria, except  $u_{\max}$ , the values of  $\phi'$  measured for each silt specimen were fairly consistent.

The undrained shear strength parameters were evaluated using the CU and UU triaxial test results from the different silt samples. Similar to the calculation of  $\phi'$ , the value of  $S_u/p$  ratio depends on the failure criteria. The results show that a unique undrained shear strength could not be determined because the samples get stronger with increasing strain.

The values of  $S_u/p$  measured from the UU triaxial tests were lower than the undrained strength ratio derived from the CU triaxial tests. The difference in  $S_u/p$  may possibly be attributed to disturbance during sampling. Results indicate that the interpretation of the undrained shear strength using UU triaxial tests was hindered by the scatter in the values of  $S_u/p$ .

The values of the undrained strength ratio from the CU triaxial tests showed dependency on the type of failure criteria. Using maximum pore pressure as failure criterion, the undrained strength ratio resulted in lower values as compared to the  $S_u/p$  ratios measured from the other failure criteria. Results indicate that the value of the undrained shear strengths of the samples increased with increasing strain.

Skempton's correlation of  $S_u/p$  to plasticity index was used to estimate the undrained strength ratio of the normally consolidated samples. Although the correlation proves to be useful for normally consolidated clays, results were too conservative when applied to silt samples.

The test results show that the changes in pore pressure highly influences the load carrying capability of the samples. A reliable method of evaluating the undrained shear strength is to determine the relationship

between the undrained strength ratio and the changes in pore pressure. Brandon et al. (1982) presented an equation relating the undrained strength ratio, effective stress friction angle, and pore pressure parameter A-bar, expressed as

$$S_u/p = \frac{\sin \phi'}{1 - (1-2A) \sin \phi'}$$

Since there is a direct proportionality between changes in pore pressure and A-bar, the equation takes into account the effect of the changes in pore pressure. Scatter in the values of the undrained strength ratio could be minimized since the value of the effective stress friction angle could be defined well from the CU triaxial tests. Using the relationship between A-bar and strain, a value of A-bar should be selected in a way that the undrained shear strength does not correspond to large values of strains.

## ABSTRACT

The purpose of this study is to investigate the primary factors which control the engineering behavior of silts. The methods of classifying silts at present do not provide much basis to infer how silts will behave in the field for design purposes.

In the course of this research study, series of UU and CU triaxial test results of different silt samples were gathered to investigate the factors that control the strength parameters of silts. Effective and total stress strength interpretation were done on the test results. The effective stress friction angle were evaluated using the CU triaxial test results. Undrained strength parameters were determined from the CU and UU triaxial test results, and comparison were performed using the undrained strength ratio  $S_u/p$ .

Silt samples which exhibit dilative behavior during undrained shear make it difficult to define failure. Because of this behavior, the test results were interpreted using different failure criteria to assess the effective stress friction angle and the undrained strength parameters.

Test results indicate that the effective stress friction angle can be evaluated using the CU triaxial test with little uncertainty.

The undrained shear strength of silt samples are influenced by the type of failure criteria. The results indicate that a unique undrained shear strength can not be determined because the samples get stronger with increasing strain. A reliable method of evaluating the undrained shear strength of silt samples is to determine the relationship between the undrained strength ratio and the changes in pore pressure.
