A ferroelectric memory device having a perovskite thin film of a rare earth manganate and processes for manufacturing the same. The perovskite thin film layer has properties consistent with high quality nonvolatile memory devices. The perovskite thin film layer can be applied by a MOCVD process, by a MOD process, or a liquid source delivery process, all of which are described.
RARE EARTH MANGANATE FILMS MADE BY METALORGANIC DECOMPOSITION OR METALORGANIC CHEMICAL VAPOR DEPOSITION FOR NONVOLATILE MEMORY DEVICES

FIELD OF THE INVENTION

The present invention relates to the field of nonvolatile memory devices using rare earth manganate films, and processes for applying the films using metalorganic decomposition and metalorganic chemical vapor deposition or liquid source delivery method.

BACKGROUND OF THE INVENTION

Semiconductor devices such as a dynamic and nonvolatile random access memory ("DRAM") have decreased in size and increased in capacity dramatically over the last 20 years. As the capacity of memory cells has increased and the size has decreased, the design of the cells has become increasingly complex in order to preserve sufficient electrical capacitance to hold the electrical charge representing the stored data.

In the past silicon dioxide has been used as the dielectric in the capacitors of DRAM cells. However, silicon dioxide has a relatively low dielectric constant of about four. There has recently been experimentation with the use of other dielectric materials in order to increase the electrical capacitance in very small and complex cells. Some of this work has focused on the use of ferroelectric materials such as lead zirconate titanate ("PZT") as the dielectric in the capacitor for the production of a ferroelectric random access memory ("FRAM").

Ferroelectrics are dielectric in nature and exhibit spontaneous polarization which can be reversed by application of a suitable electric field. The polarization in these materials responds to an external electric field in a hysteresis fashion and thereby the materials exhibit bi-stable properties which can be reversed by application of alternating polarity. This results in an internal field difference which can cause effective one-directional movement of defects like vacancies and mobile impurity ions. Since the electrode-ferroelectric interface is chemically unstable, it provides sites of lower energy to these defects relative to the bulk ferroelectric thereby causing defect entrapment at these interfaces (see Yoo, et al., "Fatigue Modeling of Lead Zirconate Titanate Thin Films", Jour. Material Sci. and Engineering). This entrapment will result in a loss in polarization in the ferroelectric.

To overcome this problem caused by defects, it is necessary to control the defect concentration, defect migration to the interface, defect entrapment at the interface, and the state of the interface itself. Lattice mismatch, poor adhesion, and work function differences between the electrode and the ferroelectric causes the interface to be chemically unstable. Therefore, it is necessary to choose an appropriate electrode which can reduce the lattice mismatch, work function differences, and the adhesion problem at the interface. The existing, commonly-used, metal electrodes such as Pt, Au, etc., do not satisfy these criteria because of the large differences in crystal structures between the electrode (metal) and the ferroelectric (ceramic), and because of the work function differences. To control the defect migration and entrapment it is necessary to reduce the abrupt compositional gradient between the electrode and the ferroelectric.

Another obstacle to integrating PZT films into the existing semiconductor process is the high temperature post-deposition annealing needed to form the desirable perovskite phase. This annealing is required because most of the as-deposited films are amorphous and they form an intermediate nonferroelectric pyrochlore phase before the formation of the perovskite phase. The transformation temperatures for initial perovskite formation and complete perovskite formation of the PZT films are functions of the compositions and the type of substrate used for deposition. Typical annealing temperatures for 33/47 films vary from 650° C. to 750° C. At these annealing temperatures, inter-diffusion among the PZT films, the contact electrodes, and the underlying metallization becomes a concern. Furthermore, thermal stress developed during the high temperature annealing may affect the long-term reliability of the device.

A variety of techniques have been used for the deposition of ferroelectric thin films. In general, the thin film deposition techniques can be divided into two major categories: (1) physical vapor deposition (PVD) and (2) chemical processes. Among the PVD techniques, the most common methods used for the deposition of ferroelectric thin films are electron beam evaporation, rf diode sputtering, rf magnetron sputtering, dc magnetron sputtering, ion beam sputtering, molecular beam epitaxy (MBE), and laser ablation. The chemical processes can be further divided into two subgroups, i.e., metalorganic chemical vapor deposition (MOCVD), and wet chemical processes including sol-gel process and metalorganic composition (MOD). The third, newer process also used in the deposition of ferroelectric thin films is the liquid source delivery method.

The PVD techniques require a high vacuum, usually better than 10⁻⁵ torr, in order to obtain a sufficient flux of atoms or ions capable of depositing onto a substrate. The advantages of the PVD techniques are (1) dry processing, (2) high purity and cleanliness, and (3) compatibility with semiconductor integrated circuit processing. However, these are offset by disadvantages such as (1) low throughput, (2) low deposition rate, (3) difficult stoichiometry control, (4) high temperature post-deposition annealing, and (5) high equipment costs.
paraelectric state, a high saturation polarization. A small metalorganic precursor has relatively high vapor pressures. They deposited PbTiO₃ films on Pt-coated silicon wafers by using TiCl₄, PbCl₂, O₂ and H₂O as source materials. Several problems arose from their studies: (1) very high evaporation temperature (700°C) was required for PbCl₂, (2) poor ferroelectric properties (Pₑ=0.16 μC/cm² and Eₑ=14.5 kV/cm), (3) poor composition uniformity in the bulk of PbTiO₃ films, and (4) crystallographic imperfections due to water and/or chloride contamination. Obviously, chlorides are not ideal precursors for the CVD process. In general, metalorganic precursors have relatively high vapor pressures at lower temperatures. By carefully selecting the organic compounds, the undesirable contaminations in the films can be completely excluded. Metalorganic compounds are now used almost exclusively for the deposition of oxide thin films.

SUMMARY OF THE INVENTION

The present invention is a memory device having a thin film perovskite layer of a rare earth manganate such as Y, Ho, Er, Tm, Yb or Lu. The device in a preferred embodiment includes a substrate of silicon, gallium arsenide or other known substrate materials, a bottom electrode, a perovskite thin film of a rare earth manganate of the formula A₃⁺MnO₃, where A=Y, Ho, Er, Tm, Yb or Lu, and a top electrode.

The rare earth manganates used with the present invention have very desirable properties for use in ferroelectric memory devices, including a high Curie temperature at which the transition occurs from the ferro-electric to the paraelectric state, a high saturation polarization, a small dielectric constant, and relatively low piezoelectric coefficients.

The rare earth manganate ferroelectric layer can be applied with either a MOCVD process or a MOD process.

The advantages of the wet chemical process are (1) molecular homogeneity, (2) high deposition rate and high throughput, (3) excellent composition control, (4) easy introduction of dopants, and (5) low capital cost, since deposition can be done in ambient condition and so no vacuum processing is needed. The major problems due to this wet process are (1) film cracking during the post-annealing process and (2) possible contamination which results in difficulty in incorporating this technique into semiconductor processing. However, because it provides a fast and easy way to produce complex oxide thin films, this wet chemical process has a very important role in the investigation of the interrelationship among the processing, the microstructure, and the property of the films.

Of all the above mentioned techniques, the metalorganic chemical vapor deposition (MOCVD) technique appears to be one of the most promising because it offers advantages of simplified apparatus, excellent film uniformity, composition control, high film densities, high deposition rates, excellent step coverage, and amenability to large scale processing. The excellent film step coverage that can be obtained by MOCVD cannot be equaled by any other technique. Purity, controllability, and precision that have been demonstrated by MOCVD are competitive with the MBE technique. More importantly, novel structures can be grown easily and precisely. MOCVD is capable of producing materials for an entire class of devices which utilize either ultra-thin layers or atomically sharp interfaces. In addition, different compositions can be fabricated using the same sources.

The first successful deposition of oxide-based ferroelectric thin films by CVD was reported by Nakagawa, et al. in "Preparation of PbTiO₃ ferroelectric thin film by chemical vapor deposition". Jpn. J. Appl. Phys., 21(1), L655 (1982). They deposited PbTiO₃ films on Pt-coated silicon wafers by using TiCl₄, PbCl₂, O₂ and H₂O as source materials. Several problems arose from their studies: (1) very high evaporation temperature (700°C) was required for PbCl₂, (2) poor ferroelectric properties (Pₑ=0.16 μC/cm² and Eₑ=14.5 kV/cm), (3) poor composition uniformity in the bulk of PbTiO₃ films, and (4) crystallographic imperfections due to water and/or chloride contamination. Obviously, chlorides are not ideal precursors for the CVD process. In general, metalorganic precursors have relatively high vapor pressures at lower temperatures. By carefully selecting the organic compounds, the undesirable contaminations in the films can be completely excluded. Metalorganic compounds are now used almost exclusively for the deposition of oxide thin films.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a schematic depiction of a memory device in accordance with the present invention.

FIG. 2 is a schematic diagram of an apparatus for use in applying ferroelectric perovskite thin films of rare earth manganates in accordance with the MOCVD process of the present invention.

FIG. 3 is a schematic diagram of an apparatus for use in applying ferroelectric perovskite thin films of rare earth manganates in accordance with the liquid source delivery process of the present invention.

FIG. 4 is a graph of an XRD pattern for a ferroelectric perovskite thin film of a rare earth manganate applied to Si in accordance with the MOD process of the present invention.

FIG. 5 is a graph of an XRD pattern for a ferroelectric perovskite thin film of a rare earth manganate applied to Si in accordance with the MOD process of the present invention.

FIG. 6 is a graph of an XRD pattern for a ferroelectric perovskite thin film of a rare earth manganate applied to Si in accordance with the MOD process of the present invention.

DETAILED DESCRIPTION OF THE INVENTION

A schematic depiction of a memory device 10 in accordance with the present invention is shown in FIG. 1. The device 10 includes a substrate 20 of a suitable material such as silicon, sapphire or gallium arsenide. The substrate 20 may be a multilayer structure having several circuit elements or a silicon chip having layers of silicon oxide, polysilicon or implanted silicon layers to form a complex integrated circuit. A conductive layer, acting as a bottom electrode 26, is applied to the substrate. A ferroelectric perovskite thin film 34 is applied over the conductive layer 26. The perovskite thin film has the composition described below. Another conductive layer, acting as a top electrode 42, is applied to the perovskite thin film. The top and bottom electrodes 42 and 26 may be for example, conducting oxide or a conducting metal.

The ferroelectric perovskite thin film 34 is a rare earth manganate with the general formula of A₃⁺MnO₃, where A=Y, Ho, Er, Tm, Yb or Lu. The device in a preferred embodiment includes a substrate of silicon, gallium arsenide or other known substrate materials, a bottom electrode, a perovskite thin film of a rare earth manganate of the formula A₃⁺MnO₃, where A=Y, Ho, Er, Tm, Yb or Lu, and a top electrode.

The rare earth manganates used with the present invention have very desirable properties for use in ferroelectric memory devices, including a high Curie temperature at which the transition occurs from the ferro-electric to the paraelectric state, a high saturation polarization, a small dielectric constant, and relatively low piezoelectric coefficients.

The rare earth manganate ferroelectric layer can be applied with either a MOCVD process or a MOD process.

The MOCVD process utilizes precursors of Y(thd)₃ where thd=C₁₁H₁₈O₂, and (CH₃CH₂MnCO₃)₉ with N₂ as a carrier gas and O₂ as a dilute gas. The MOCVD process produces a thin film with excellent film uniformity, composition control, high density, high deposition rates and excellent step coverage, utilizing fairly simple equipment that is amenable to large scale processing.

The MOD process for applying the rare earth manganate ferroelectric layer produces a film with high molecular homogeneity, and allows for a high deposition, high throughput, excellent composition control and easy introduction of dopants. Solvents of methanol, methoxythanol, 1-propanol or ethylcel glycol are used.
ization (P = 6 μC/cm²) and a small dielectric constant (ε = 20 at 20°C). Further, it is expected that these compounds will have relatively small piezoelectric coefficients. Because manganese prefers higher oxidation states in oxidizing atmospheres, the oxygen vacancy concentration is expected to be small. These properties of rare earth manganates are consistent with fatigue-free, high retention, ferroelectric memories. Some of the properties of rare earth manganates (specifically, YMnO₃) are tabulated as follows:

The perovskite thin film 34 of a rare earth manganate can be applied to the bottom electrode by metalorganic chemical vapor deposition ("MOCVD") or by metalorganic decomposition ("MOD"). The MOCVD process offers the advantages of a simplified apparatus, excellent film uniformity, composition control, high film densities, high deposition rates, excellent step coverage, and amenability to large scale processing. It is believed that the excellent film step coverage that can be obtained by MOCVD cannot be equalled by any other known technique. Also, novel structure can be grown easily and precisely with MOCVD, and MOCVD is capable of producing materials for an entire class of memory devices that utilize either ultra-thin layers or atomically sharp interfaces.

A schematic diagram of an apparatus 70 for use in applying ferroelectric perovskite thin films of rare earth manganates is shown in FIG. 2. The precursor materials are packaged in stainless steel bubblers 72 and 73, each having two connects 74 and 76, and 75 and 77, respectively. One connect 74 runs to be the reaction chamber 78 while the other connect 76 runs to a set of N₂ gas cylinders 80 with mass flow controllers. The reaction chamber 78 is a stainless steel tube. Heating of the substrate is achieved with a reaction chamber heater 84 or, alternatively, with a substrate heater. Oxygen is added by an oxygen source 88.

A MOCVD apparatus such as the one described above was used to deposit a ferroelectric perovskite thin film of YMnO₃ under the following conditions:

<table>
<thead>
<tr>
<th>Precursors</th>
<th>Y(thd)₂(CH₃C₅H₄)Mn(CO)₃</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bubbler Temp.</td>
<td>130–150°C</td>
</tr>
<tr>
<td>Carrier Gas</td>
<td>N₂, 20–40 sccm</td>
</tr>
<tr>
<td>Dilute Gas</td>
<td>O₂, 500–1000 sccm</td>
</tr>
<tr>
<td>Deposition Temp.</td>
<td>500°C</td>
</tr>
</tbody>
</table>

These conditions produce a deposition rate of 10–20 nm/min.

In a MOD process for applying ferroelectric perovskite thin films of rare earth manganates, there are disadvantages related to film cracking during the post-annealing process and also possible contamination. However, an MOD process has the advantages of producing a film with high molecular homogeneity. It also allows for a high deposition rate and high throughput, excellent composition control, and easy introduction of dopants. In addition, the equipment costs are relatively low since the deposition can be done in ambient condition without vacuum processing. Table 1 below shows the results of a MOD process for the production of a ferroelectric perovskite thin film of YMnO₃ under several conditions, using Yttrium Acetate and Manganese(III) Acetate as starting materials.

The XRD patterns for the resulting films are in FIGS. 4–6. FIG. 4 shows the XRD pattern of a thin film of YMnO₃ on Si; FIG. 5 shows the XRD pattern of a thin film of YMnO₃ on Pt; and FIG. 6 shows the XRD pattern of a thin film of YMnO₃ on sapphire.
What is claimed is:
1. A memory device, comprising:
   a substrate;
   a film of a rare earth manganate; and
   at least one electrode on the film; wherein
   said film is produced by a process of metalorganic chemical vapor deposition including as a precursor at least one of (CH₃C₅H₄)Mn(CO)₃; A(C₁₁H₁₉O₂)₃, A being selected from the group consisting of Y, Ho, Er, Tb, and Lu;
   an alkyl of an element selected from the group consisting of Mn, Y, Ho, Er, Tb, and Lu;
   an alkoxide of an element selected from the group consisting of Mn, Y, Ho, Er, Tb, and Lu;
   a beta-diketonate of an element selected from the group consisting of Mn, Y, Ho, Er, Tb, and Lu;

2. The memory device of claim 1, comprising:
   a substrate;
   a film of a rare earth manganate; and
   at least one electrode on the film of the formula A<sup>3+</sup>MnO₃, where A is selected from the class consisting of Y, Ho, Er, Tb, and Lu; wherein
   said film is produced by a process of metalorganic decomposition including use of at least one of yttrium acetate and manganese and manganese(III) acetate as a starting material.
