**SHRINKAGE OF LATEX-MODIFIED AND MICROSILICA CONCRETE OVERLAY MIXTURES**  
**Patricia Buchanan**

**(ABSTRACT)**

Highway bridge decks are often overlaid to extend service life by reducing the rate of chloride ion ingress and the rate of corrosion of reinforcing steel in the sound chloride-contaminated concrete that is left in-place. Bridge deck overlays in Virginia are usually either latex-modified concrete or microsilica concrete, and both types of overlay are considered equivalent in terms of performance. However, the latex-modified concrete overlays are more expensive to construct than the microsilica concrete overlays. Thus, it is important to determine if these overlays do perform equivalently to ensure that short-term savings do not lead to higher long-term costs.

Shrinkage is one of the overlay performance parameters. Shrinkage is a three-dimensional deformation of concrete that results in an overall reduction in volume. Total shrinkage may be measured under either restrained or unrestrained conditions.

This research examines the shrinkage performances of Virginia Department of Transportation-approved latex-modified and microsilica concrete overlay mixtures and was conducted on both field-sampled and laboratory-fabricated restrained and unrestrained specimens. Based on crack and delamination surveys of sampled bridge decks and laboratory test results, a shrinkage performance-based specification for the Virginia Department of Transportation was developed.

There was no significant difference between the unrestrained shrinkage values of latex-modified and microsilica concrete overlay mixtures for the specified time periods. Restrained microsilica concrete specimens generally cracked earlier and more frequently than restrained latex-modified concrete specimens. However, the bridge deck crack and delamination surveys show that construction conditions and quality and traffic type and frequency may have a greater effect on cracking than the overlay material.

## ACKNOWLEDGEMENTS

First, I would like to thank Dr. Richard Weyers for his invaluable advice and assistance with this project. I also have a great appreciation for Dr. Thomas Cousins and Dr. Carin Roberts-Wollmann for their guidance as members of my committee.

I am grateful to Mr. Michael Sprinkel for his guidance as a member of my committee as well as the Virginia Transportation Research Council for funding this project. Special thanks go to the VTRC technicians who helped with sample collection, testing, and bridge deck crack and delamination surveys.

I am deeply indebted to David Mokarem for teaching me everything I needed to know about the testing equipment and for all his help with specimen preparation. I could not have completed this research without his help, advice, and patience.

I would also like to thank Dr. Christine Anderson-Cook and Juan Li (Julie) of the Statistics Department for helping me gain a better understanding of statistics and performing several analyses.

Many thanks go to the faculty and staff of the Structural Engineering and Materials Department for valuable learning experiences and support over the past six years.

I would like to express my gratitude to my parents, Dr. Ronald Buchanan and Darlene Buchanan, and my sisters, Sharon, Theresa, and Stephanie, for their love, support, and patience as one year of graduate school became two years.

I am deeply grateful to my fiancé, Matthew Aguirre, for his love, support, understanding, patience, and for allowing me to monopolize his computer.

Finally, I would also like to thank all my friends, Sarah Manning, Anna Leung, William Schooley, Jean-Philippe Guizol, Michael Brown, Trevor Kirkpatrick, and Ed Vincent for their support and help throughout my entire college career.

## INTRODUCTION

Highway bridges are often overlaid to reduce the rate of chloride ion diffusion to the reinforcing steel and extend the service life of the bridge. In Virginia, these overlays are generally either a latex-modified concrete (LMC) or a microsilica concrete (MSC). Both types of overlay mixture are considered to perform equivalently despite a lack of research into their comparative performances. However, they are not equivalent in cost. A LMC overlay mixture has to be mixed on-site in a mobile mixer, which is more expensive than a MSC overlay mixture that can be mixed at any concrete plant and trucked to the site. Thus, most new overlays in Virginia are MSC. It is therefore important to determine if both LMC and MSC overlays do, in fact, perform equivalently to ensure that short-term savings do not lead to higher long-term costs.

One performance assessment parameter of concrete overlays is its shrinkage. Shrinkage is a three-dimensional deformation of concrete that results in an overall reduction in volume. Typically, the shrinkage of a concrete specimen is expressed as a linear strain since one of the dimensions is significantly larger than the other two and “the effects of shrinkage are greatest in the largest dimension” (Aïtcin, et al, 1997). As these internal strains increase, so does the potential for cracking (Shah, et al, 1998). Cracks may ease the ingress of moisture, oxygen, and chloride ions to the depth of the reinforcing steel. This, in turn, may lead to an increase in the rate of corrosion of the steel and a reduction in service life.

There are four types of shrinkage: plastic, autogenous, drying, and carbonation. Plastic shrinkage is caused by water loss from the surface of concrete within a few hours of placement while the concrete is still plastic and before it gains any significant strength (Soroushian and Ravanbakhsh, 1998). Autogenous shrinkage takes place as a result of cement hydration and develops isotropically within the concrete mass (Aïtcin, et al, 1997). Drying shrinkage occurs in the hardened concrete as free water evaporates from the capillary pores (Tazawa and Yonekura, 1987). Carbonation shrinkage is poorly understood but is the result of carbonation of the hydrated cement products (Soroka, 1979). Total shrinkage can be measured under either restrained or unrestrained conditions.

This research examines the shrinkage performances of Virginia Department of Transportation-approved LMC and MSC overlay mixtures. The research was conducted on both field-sampled and laboratory-fabricated specimens. The results of this research were used to develop a suggested shrinkage performance specification.

## PURPOSE AND SCOPE

There are three objectives of this research. The first is to assess the shrinkage strains and shrinkage cracking of both latex-modified and microsilica concrete bridge deck overlay mixtures. The second is to determine whether or not microsilica concrete overlays are equivalent to latex-modified concrete overlays from a shrinkage standpoint. The final objective is to develop a shrinkage performance specification for LMC and MSC overlays in order to minimize cracking.

To accomplish these objectives, field samples were collected from six bridge overlay projects in Virginia. Three sets of samples were from LMC overlays and three were from MSC overlays. Laboratory specimens based on the mixture designs of the field overlays were made and subjected to different curing regimes. Both restrained and unrestrained shrinkage specimens were tested. Approximately half of each mixture's unrestrained specimens were stored in a controlled temperature and relative humidity environment while others were stored in ambient air in the laboratory. In addition to shrinkage testing, specimens were cast for compressive strength and modulus of elasticity; rapid permeability tests were also conducted to aid in the development of the shrinkage performance specification.

## METHODS AND MATERIALS

The restrained drying shrinkage of the concrete specimens was tested per AASHTO PP34-99, Practice for Estimating the Crack Tendency of Concrete (AASHTO Provisional, 2000). This test method requires casting a 76 mm wide by 152 mm high concrete ring around a 305 mm diameter steel ring, as shown in Figure 1. Strain gages are attached to the interior of the steel ring at quarter points to monitor the strain caused by the shrinkage of the concrete. As the concrete shrinks, the steel ring is placed in compression; the resulting compressive strain should decrease as the concrete cracks. These cracks were visually monitored approximately biweekly for changes in length and width. Crack widths were measured using a crack comparator and crack lengths were measured with a standard ruler.

**Figure 1: AASHTO PP34-99 Specimen Construction**

The unrestrained shrinkage testing was conducted on prisms measuring 75 mm by 75 mm by 286 mm per ASTM C157, Standard Test Method for Length Change of Hardened Hydraulic-Cement Mortar and Concrete (ASTM, 2001). For this test method, the length change of each prism is measured. The measurements were made with a comparator every day for the first seven days and then once every seven days thereafter for a minimum of ninety days. These length changes were then converted to percent shrinkage.

The compressive strength was tested according to ASTM C 39, Compressive Strength of Cylindrical Concrete Specimens, using steel end caps and neoprene pads (ASTM, 2001). The 102 mm by 203 mm cylinders were tested at 7, 28, 56, and 90 days of age.

The modulus of elasticity was measured per ASTM C 469, Standard Test Method for Static Modulus of Elasticity and Poisson’s Ration of Concrete in Compression (ASTM, 2001). One 152 mm by 305 mm cylinder was cast from each truck sampled for field samples and one for each laboratory mixture. Each cylinder was tested at 7, 28, 56, and 90 days.

The Virginia Transportation Research Council performed the rapid permeability tests according to AASHTO T277, Electrical Indication of Concrete’s Ability to Resist Chloride Ion Penetration (AASHTO, 2000). The test was modified for the LMC specimens to allow formation of the polymer film. The 102 mm by 203 mm cylinders were tested at 7, 28, and 90 days.

### Field Overlay Sampling

The Virginia Department of Transportation (VDOT)-approved mixture proportions for the field samples are summarized in Table 1 and are for one cubic meter of concrete based on SSD conditions.

**Table 1: Field Sample Mixture Designs**

|              | Number of Samples | Specimens/Sample |       |            | Number of Samples | Specimens/Sample |       |
|              |                   | Prisms           | Rings |            |                   | Prisms           | Rings |
| Rt. 1 NBL    | 3                 | 2                | 2     | Rt. 56     | 3                 | 2                | 2     |
| Rt. 1 SBL    | 3                 | 4                | 2     | Rt. 150/10 | 3                 | 4                | 2     |
| Wilson Creek | 3                 | 6                | 2     | Rt. 150/FC | 3                 | 6                | 2     |

Both sets of samples from Rt. 1 near Doswell, Virginia, were from the same bridge but were taken from different placements, one from the northbound lane overlay placement and one from the southbound lane overlay placement. This bridge is located near a quarry; the southbound lanes carry loaded quarry trucks that return over the northbound lane empty. In contrast, the Wilson Creek Bridge in Blacksburg, Virginia, experiences little traffic since it is part of a test roadway. The Wilson Creek Bridge was the only newly constructed bridge sampled as part of this research. The 7 bag overlay mixture sampled from this bridge was a replacement for the original 7.5 bag overlay mixture that had been placed previously. The original overlay experienced a large amount of cracking soon after placement, so it was removed and the overlay mixture was redesigned.

The Rt.56 bridge is located in rural Nelson County, Virginia, and experiences little traffic volume although it does experience some heavy truck traffic due to loaded log trucks. In contrast, the sampled bridges from Rt. 150 outside Richmond, Virginia, experience heavy traffic volumes but this traffic consists mainly of cars and light trucks.

The field samples were used to compare the effects of the contractor as well as to determine whether there is a significant difference in the overall performances of LMC and MSC overlays. Both overlays from Route 150 were performed by the same contractor, as were both overlays sampled from Route 1. With the exception of the specimens from the Wilson Creek Bridge, half of the prisms were stored at a controlled temperature of  $23^{\circ}\text{C} \pm 2^{\circ}\text{C}$  and relative humidity of  $50\% \pm 4\%$ , while the remaining specimens were stored in uncontrolled laboratory air. Temperature and relative humidity variations in the laboratory were measured and recorded. For the Wilson Creek Bridge prism specimens, two specimens from each sampling site were stored in the controlled environment with the remaining four stored in the uncontrolled environment.

Field samples were collected for restrained and unrestrained shrinkage, compressive strength, modulus of elasticity, and permeability testing. All MSC permeability specimens were moist cured for three days, then were stored in  $38^{\circ}\text{C}$  water except while the specimens were being tested. All LMC permeability specimens were moist cured for two days, then were stored in  $38^{\circ}\text{C}$  air except while the specimens were being tested to allow the polymer film to form.

After nine to twelve months, the bridge decks from which field samples were taken were examined for cracking and delaminations. The purpose of this inspection was to compare field performance with laboratory results.

#### **Laboratory Overlay Sampling**

The mixture designs for laboratory specimens are summarized in Table 3 and are for a one cubic meter batch. The mixtures designated as SF-L3, SF-L7, and LMC-L2 are proportioned to represent the field overlay mixtures. The final number in these designations refers to the number of days the specimens from that mixture are subjected to moist curing. All of the LMC-WCL mixtures are based on the mixture proportions used on the Wilson Creek Bridge. The final number in these designations refers to the number of bags of cement used in

the mixture for one cubic yard of concrete. The LMC-WCL mixtures were subjected to two days of moist curing.

**Table 3: Laboratory Mixture Proportions, SSD Conditions**

|                        | SF-L3, L7 | LMC-L2 | LMC-WCL-7.5 | LMC-WCL-7 | LMC-WCL-6.5 | LMC-WCL-6.5A | LMC-WCL-6.5B |
|------------------------|-----------|--------|-------------|-----------|-------------|--------------|--------------|
| Cement: Type I/II (kg) | 377       | 388    | 418         | 390       | 362         | 362          | 362          |
| Silica Fume (kg)       | 30        | 0      | 0           | 0         | 0           | 0            | 0            |

| Water (kg)             | 163       | 87     | 86          | 86        | 86          | 98           | 73           |
| AEA (mL)               | 193       | 0      | 0           | 0         | 0           | 0            | 0            |
| Water Reducer (mL)     | 0         | 0      | 0           | 0         | 0           | 0            | 0            |
| HRWR (mL)              | 2650      | 0      | 0           | 0         | 0           | 0            | 0            |
| Latex (kg)             | 0         | 120    | 130         | 121       | 104         | 81           | 114          |
| w/cm                   | 0.40      | 0.38   | 0.36        | 0.38      | 0.38        | 0.38         | 0.36         |

The LMC laboratory specimens were assembled according to the test matrix outlined in Table 4. Half of all the prism specimens were stored in the controlled environment; the remaining specimens were stored in the uncontrolled environment.

**Table 4: LMC Overlay Laboratory Test Matrix**

| Cement Content     | Number of Batches | Specimens/Batch |       |
|--------------------|-------------------|-----------------|-------|
|                    |                   | Prisms          | Rings |
| 7.5 Bag Mixture    | 2                 | 6               | 2     |
| 7 Bag Mixture      | 2                 | 6               | 2     |
| 6.5 Bag Mixture    | 2                 | 6               | 2     |
| Latex Content      |                   |                 |       |
| 9.5 L/bag          | 2                 | 6               | 2     |
| 13.2 L/bag         | 2                 | 6               | 2     |
| Water/Cement Ratio |                   |                 |       |
| 0.36               | 2                 | 6               | 2     |
| 0.38               | 2                 | 6               | 2     |

The MSC laboratory specimens were assembled according to the test matrix shown in Table 5. Half of all the prism specimens were stored in the controlled environment and the remaining specimens were stored in the uncontrolled environment.

**Table 5: MSC Overlay Laboratory Test Matrix**

| Curing Regime | Number of Batches | Specimens/Batch |       |
|---------------|-------------------|-----------------|-------|
|               |                   | Prisms          | Rings |
| 3 Days        | 2                 | 6               | 2     |
| 7 Days        | 2                 | 6               | 2     |

Curing regimes for the permeability specimens also varied; these are outlined in Table 6.

**Table 6: Curing Regimes for Permeability Testing**

|                                 | Cylinders/Batch | Moist Cure (days) | Lab Air (days) | 38°C Air (days) | 38°C Water (days) |
|---------------------------------|-----------------|-------------------|----------------|-----------------|-------------------|
| MSC Overlay Laboratory Mixtures | 1               | 3                 | 4              | 0               | 83                |
|                                 | 1               | 2                 | 5              | 0               | 83                |
|                                 | 1               | 3                 | 4              | 0               | 21                |
|                                 | 1               | 2                 | 26             | 0               | 0                 |
|                                 | 1               | 3                 | 25             | 0               | 0                 |
| LMC Overlay Laboratory Mixtures | 1               | 2                 | 5              | 83              | 0                 |
|                                 | 1               | 3                 | 4              | 83              | 0                 |
|                                 | 1               | 2                 | 5              | 0               | 21                |
|                                 | 1               | 2                 | 26             | 0               | 0                 |
|                                 | 1               | 3                 | 25             | 0               | 0                 |

A test matrix showing the specimens collected or cast from each field and laboratory mixture for each test conducted is given in Appendix H.

## RESULTS

Statistical analyses including modified t-tests and contrast tests performed using SAS on the data showed no significant differences at the 95% confidence level (CL) between results obtained from specimens stored in the controlled environment and specimens stored in the ambient laboratory air, nor were there significant differences between batches. Thus, the data were combined to provide a larger sample size for comparisons. The results discussed in this section are from the combined data and include 95% confidence intervals.

Crack widths for each set of samples were combined for simplification; the same was done for crack lengths for each set of samples. These were then compared to determine which mixtures experienced more severe cracking.

The results of compressive strength and modulus of elasticity testing are given in Appendix D. Results of rapid permeability testing are given in Appendix E.

### Field Overlays

#### LMC Overlays

The samples taken from the northbound lane of Route 1 north of Richmond, Virginia, were designated LMC-1.1. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.041\% \pm 0.019\%$ . None of the restrained specimens cracked.

The samples taken from the southbound lane of Route 1 north of Richmond, Virginia, were designated LMC-1.2. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.047\% \pm 0.009\%$ . None of the restrained specimens cracked.

The samples taken from the Wilson Creek Bridge in Blacksburg, Virginia, were designated LMC-WC. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.089\% \pm 0.018\%$ . The first crack in the restrained specimens was visually observed at an age of 33 days. At approximately 180 days, the combined crack widths on all restrained specimens reached 2.39 mm and the combined crack lengths was 1050 mm. All six specimens had at least one crack, with one specimen cracked in two places.

The unrestrained shrinkage as a function of time for the field LMC overlay samples is summarized in Figure 2 and numerically at ages 28 and 90 days in Table 7. Table 8 presents a summary of the ring crack results at 28, 90, and 180 days. Figure 3 presents a summary of the combined crack width and length results for the LMC-WC restrained ring specimens.

#### MSC Overlays

The samples taken from the westbound lane of Route 56 in Nelson County, Virginia, were designated SF-56. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.083\% \pm 0.013\%$ . The first crack in the restrained specimens was visually observed at an age of 64 days. At approximately 180 days, the total number of cracks was 20

and all restrained specimens had cracked. The combined crack widths totaled 2.34 mm and the combined crack lengths reached 1524 mm.

The samples taken from the Route 150 bridge over Route 10 south of Richmond, Virginia, were designated SF-150/10. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.057\% \pm 0.013\%$ . The first crack in the restrained specimens was visually observed at an age of 58 days. At approximately 180 days, the total number of cracks was 14 and all restrained specimens had cracked. The combined crack widths totaled 2.40 mm and the combined crack lengths totaled 1388 mm.

Figure 2: Field LMC Overlay Unrestrained Shrinkage, Average and 95% CL

The samples taken from the Route 150 bridge over Falling Creek south of Richmond, Virginia, were designated SF-150/FC. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.086\% \pm 0.014\%$ . The first crack in the restrained specimens was visually observed at an age of 30 days. At approximately 180 days, the total number of cracks was 9 and all restrained specimens had cracked. The combined crack widths totaled 1.96 mm and the combined crack lengths totaled 1295 mm.

The unrestrained shrinkage as a function of time for the field MSC overlay samples is summarized in Figure 4 and numerically at ages 28 and 90 days in Table 7. Numerical results for ages 28, 90, and 180 days are presented in Table 8. Figures 5, 6, and 7 present the combined crack width and length results for the restrained ring specimens for SF-56, SF-150/10, and SF-150/FC, respectively.

**Table 7: Unrestrained Shrinkage Values**

| Age (days) | Average Unrestrained Shrinkage Values at 95% CL (%) |             |             |             |             |             |
|------------|---|-------------|-------------|-------------|-------------|-------------|
|            | LMC-1.1   | LMC-1.2     | LMC-WC      | SF-56       | SF-150/10   | SF-150/FC   |
| 28         | 0.03 ± 0.02   | 0.03 ± 0.01 | 0.06 ± 0.01 | 0.07 ± 0.02 | 0.04 ± 0.01 | 0.07 ± 0.01 |
| 90         | 0.04 ± 0.02   | 0.05 ± 0.01 | 0.09 ± 0.02 | 0.08 ± 0.01 | 0.06 ± 0.01 | 0.09 ± 0.01 |

**Table 8: Crack Data Summary**

| Mixture   | Total Number of Rings | Number of Cracked Rings |         |          | Combined Crack Width (mm) |         |          | Combined Crack Length (mm) |         |          |
|-----------|-----------------------|-------------------------|---------|----------|---------------------------|---------|----------|----------------------------|---------|----------|
|           |                       | 28 days                 | 90 days | 180 days | 28 days                   | 90 days | 180 days | 28 days                    | 90 days | 180 days |

### Laboratory Mixtures

#### LMC Mixtures

The laboratory LMC overlay mixture based on the 7.5 bag Wilson Creek Bridge mixture design was designated LMC-WCL-7.5. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.100\% \pm 0.012\%$ . The first crack in the restrained specimens was visually observed at an age of 26 days. At approximately 180 days, the total number of cracks was 4 and all of the restrained specimens had cracked. The combined crack widths totaled 2.43 mm and the combined crack lengths totaled 600 mm.

The laboratory LMC overlay mixture based on the 7 bag Wilson Creek Bridge mixture design was designated LMC-WCL-7. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.092\% \pm 0.013\%$ . The first crack in the restrained specimens was visually observed at an age of 39 days. At approximately 180 days, the total number of cracks was 5 and all of the restrained specimens had cracked. The combined crack widths totaled 1.96 mm and the combined crack lengths totaled 680 mm.

The laboratory LMC overlay mixture based on the VDOT specifications was designated LMC-L2. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.055\% \pm 0.006\%$ . The first crack in the restrained specimens was visually observed at an age of 144 days. At approximately 180 days, the total number of cracks was 2 and 2 of the 4 restrained specimens had cracked. The combined crack widths totaled 0.16 mm and the combined crack lengths totaled 300 mm.

The 6.5 bag laboratory LMC overlay mixture using 13.2 L of latex per bag of cement and having a water-cement ratio (w/c) of 0.38 was designated LMC-WCL-6.5. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.082\% \pm 0.016\%$ . The first crack in the restrained specimens was visually observed at an age of 39 days. At approximately 180 days, the total number of cracks was 9 and all the restrained specimens had cracked. The combined crack widths totaled 1.72 mm and the combined crack lengths totaled 1320 mm.

The 6.5 bag laboratory LMC overlay mixture using 9.5 L of latex per bag of cement and having a w/c of 0.38 was designated LMC-WCL-6.5A. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.074\% \pm 0.009\%$ . No restrained specimens were cast for this mixture.

The 6.5 bag laboratory LMC overlay mixture using 13.2 L of latex per bag of cement and having a w/c of 0.36 was designated LMC-WCL-6.5B. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.047\% \pm 0.009\%$ . No restrained specimens were cast for this mixture.

Figure 8 presents the unrestrained shrinkage as a function of time for LMC-WCL-7.5, LMC-WCL-7, and LMC-WCL-6.5B. Figure 9 presents the unrestrained shrinkage as a function of time for LMC-L2, LMC-WCL-6.5, and LMC-6.5A. Figures 10, 11, 12, and 13 show summaries of the crack data from the restrained ring specimens for LMC-WCL-7.5, LMC-WCL-7, LMC-L2, and LMC-WCL-6.5, respectively.

#### MSC Mixtures

The laboratory MSC overlay mixture that was moist cured for 3 days was designated SF-L3. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.061\% \pm 0.007\%$ . The first crack in the restrained specimens was visually observed at an age of 144 days. At 180 days, only one specimen was cracked in one location. The crack was 0.080 mm wide and 110 mm in length.

The laboratory MSC overlay mixture that was moist cured for 7 days was designated SF-L7. At a shrinkage age of 90 days, the unrestrained shrinkage of the specimens averaged  $0.056\% \pm 0.008\%$ . At 180 days, none of the restrained specimens had cracked.

The unrestrained shrinkage as a function of time for the laboratory MSC overlay samples is summarized in Figure 14. Figure 15 presents the combined crack width and length for the restrained ring specimens for SF-L3.

## DISCUSSION

### Field Overlays

As shown in Figure 2, the LMC overlay specimens from the Wilson Creek Bridge experienced greater unrestrained shrinkage than either overlay from Route 1. In addition, the restrained specimens from Wilson Creek developed large cracks at an early age, while the Route 1 restrained specimens never cracked. The Wilson Creek Bridge deck also exhibited a significantly larger amount of linear and pattern cracking than the Route 1 LMC overlays. In comparison, there is little difference between crack frequencies of the Route 1 overlays, as shown in Table 9.

The significant difference between shrinkage and cracking performance of the Route 1 and Wilson Creek LMC overlays are related to a combination of construction quality (contractor workmanship) and traffic conditions. The Wilson Creek Bridge is part of a test roadway and has experienced relatively little traffic in the time period between overlay placement and field inspections. The deck was too wet at the beginning of placement and the measured concrete slumps ranged from 108mm when the inspector was on-site to 229 mm after the inspector left. There is little doubt that the amount of shrinkage and cracking of this LMC overlay is the result of poor workmanship.

However, the difference in linear cracking in the Route 1 northbound and southbound lanes is the result of traffic conditions. Loaded stone quarry trucks travel over the southbound lanes and return over the northbound lanes empty. Since the shrinkage test results were the same for these two overlay placements, the difference in linear cracking appears to be related to the heavier loading of the Route 1 SB lanes.

There is less variation between the MSC overlay specimens. The unrestrained shrinkage values for SF-150/10 are less than those for the other MSC overlays sampled, but not significantly less. All of the MSC restrained shrinkage specimens had begun cracking by 90 days, and by 180 days, the SF-56 restrained specimens had experienced the most cracking. The combined crack widths for SF-56 and SF-150/10 were very similar. The Route 56 and Route 150 over Falling Creek bridge decks experienced similar amounts of cracking; the Route 150 over Route 10 bridge overlay experienced significantly more cracking than the other two MSC overlays, as shown in Table 9.

Again, the difference in cracking in the MSC overlays appears to be more of the result of quality of construction than shrinkage of the sampled mixtures. Traffic conditions for the Route 150 bridges over Route 10 and Falling Creek are approximately the same, with very heavy traffic count but very little truck traffic. The bridge over Route 10 carries northbound traffic while the Falling Creek Bridge carries southbound traffic; the two bridges are less than three kilometers apart. Placement and curing of Route 150 over Route 10 overlay was done in the early to late morning hours under less than ideal conditions. The Route 150 over Falling Creek overlay was placed during the night and early morning hours, as was the Route 56 overlay. Unlike Route 150, Route 56 is a rural route with a low traffic count with some heavy truck traffic (loaded log trucks).

A comparison of the unrestrained shrinkage versus time for the overall average values of shrinkage for LMC and MSC is shown in Figure 16. The variations are large, so to eliminate the effect of differing contractors, the unrestrained shrinkage over time for the average values of shrinkage for LMC overlays by the same contractor and MSC overlays by the same contractor is shown in Figure 17. As shown, there does not appear to be a significant difference between the unrestrained shrinkage values of LMC and MSC overlays. This was verified by statistical analysis at the 95% confidence level. However, there is a significant difference between the LMC and MSC restrained specimens. While all of the MSC specimens cracked by 180 days, the only LMC specimens to crack by that age were those taken from the Wilson Creek Bridge, once again demonstrating the influence of workmanship. Although the MSC overlay specimens exhibited more linear shrinkage and restrained cracking, this does not translate into more deck cracking.

Figure 16: LMC and MSC Average Field Overlay Unrestrained Shrinkage

Figure 17: Average LMC and MSC Same Contractors Field Overlay Unrestrained Shrinkage

Laboratory Overlay Mixtures

**Influence of Cement Content**

Figure 8 presents the unrestrained shrinkage values for LMC-WCL-7.5, LMC-WCL-7, and LMC-WCL-6.5B. These mixtures have the same latex content of 13.2 L/bag of cement. The w/c for each are similar. The 7.5 bag and 7 bag Wilson Creek mixtures have significantly larger values of unrestrained shrinkage than those of the LMC-WCL-6.5B mixture. The unrestrained shrinkage values for the 7.5 bag and 7 bag mixtures are not significantly different at any age. Results from the restrained shrinkage testing are similar to those of the unrestrained shrinkage. All of the restrained specimens for both the 7.5 bag and 7 bag mixtures had cracked by 180 days, although the LMC-WCL-7.5 specimens began cracking at an earlier age than the LMC-WCL-7 specimens. No restrained specimens were cast from the LMC-WCL-6.5B mixture.

**Influence of Different 7 Bag Mixture Designs**

A comparison of the unrestrained shrinkage values for LMC-L2 and LMC-WCL-7 is given in Figure 18. Both mixtures have the same cement and latex contents as well as the same w/c. However, the LMC-WCL-7 mixture experienced significantly greater shrinkage than the LMC-L2 mixture. This is also shown in a comparison of the restrained shrinkage results. The LMC-WCL-7 ring specimens began cracking at an age of 39 days and all had cracked by 180 days. The LMC-L2 ring specimens began cracking at 144 days and only half of the specimens

had cracked by 180 days. These mixtures are very similar; the primary difference between them is the type of latex used. The 7.5 bag and 7 bag Wilson Creek mixtures both used a BASF latex, while the LMC-WCL-6.5, LMC-WCL-6.5A, LMC-WCL-6.5B, and LMC-L2 mixtures used a Dow latex.

Figure 18: Comparison of 7 Bag Mixtures, Unrestrained Shrinkage

**Influence of Latex Content**

Figure 19 examines the unrestrained shrinkage of LMC-WCL-6.5A, which has 9.5 L of latex/bag of cement, and LMC-WCL-6.5, which has 13.2 L of latex/bag of cement. Both mixtures have the same w/c of 0.38 and the same cement content. There is no significant difference between the shrinkage values of LMC-WCL-6.5A and LMC-WCL-6.5.

**Influence of w/c**

The effect of w/c on unrestrained shrinkage is shown in Figure 20. Both LMC-WCL-6.5 and LMC-WCL-6.5B have the same cement and latex contents. The LMC-WCL-6.5 specimens, with a w/c of 0.38, exhibited significantly greater shrinkage than the LMC-WCL-6.5B specimens, with a w/c of 0.36.

Figure 19: Comparison of Latex Content, Unrestrained Shrinkage

Figure 20: Comparison of w/c, Unrestrained Shrinkage

### Influence of Curing Time

The effect of curing regime on the unrestrained shrinkage of the laboratory MSC overlay mixture is shown in Figure 14. Both mixtures had the same cement and microsilica contents as well as the same w/c. At 7 and 28 days, there are significant differences between the shrinkage values; however, by 56 days, there is no significant difference between the unrestrained shrinkage values. These results are similar to the restrained shrinkage testing results. Only one of the SF-L3 restrained specimens cracked by 180 days, while none of the SF-L7 specimens cracked.

### Comparison of Laboratory LMC and MSC Mixtures

A comparison of LMC-L2 and SF-L7 is shown in Figure 21 to contrast the unrestrained shrinkage values of laboratory LMC and MSC mixtures. There is no significant difference in the unrestrained shrinkage values of these mixtures although some differences do exist in the restrained shrinkage results. By 180 days, half of the LMC-L2 ring specimens were cracked while none of the SF-L7 specimens were cracked. This illustrates the influence of construction conditions on the shrinkage and cracking of MSC and LMC mixtures. The field-sampled MSC mixtures exhibited a significantly larger amount of shrinkage and cracking than the laboratory-cast mixtures, which is probably a result of tighter mixture, and mixing controls in the laboratory.

Figure 21: LMC and MSC Laboratory Overlay Mixtures, Average Unrestrained Shrinkage

## CONCLUSIONS

Increasing the cement content increases the amount of shrinkage. However, the differences between shrinkage values for the 7.5 bag and 7 bag LMC overlay mixtures from the Wilson Creek Bridge are not significant.

Decreasing the latex content of a LMC overlay mixture does not have a significant effect on the amount of shrinkage.

Increasing the w/c of a LMC overlay mixture significantly increases the amount of shrinkage.

Increasing the moist curing time from 3 to 7 days for a MSC overlays mixture has no significant effect on long-term shrinkage although the effect on shrinkage values prior to 56 days is significant. The difference in curing regimes has little effect on shrinkage cracking.

Mixtures with unrestrained shrinkage values of 0.05% with a 95% upper confidence limit (UCL) of 0.06% at an age of 90 days and 0.04% with a 95%UCL of 0.05% at an age of 28 days experience less cracking as determined by AASHTO PP34-99.

Both field and laboratory specimens show no significant difference between LMC and MSC overlay mixtures' shrinkage values. However, shrinkage cracking is more prevalent and severe in the field MSC overlay specimens. The bridge deck crack and delamination surveys show that cracking results more from construction conditions and quality and traffic type and frequency than from the overlay material.

## RECOMMENDATIONS

Further research should be conducted on different MSC overlay mixtures exposed to different curing regimes to determine whether the significant short-term differences in shrinkage values have a significant effect on cracking.

The rapid permeability test procedure (AASHTO T277) should be modified for LMC mixtures. After 1 day of moist curing, LMC specimens should be stored in 38°C air for 27 days to allow the polymer film to form. MSC specimens should be moist cured for 7 days and then stored in 38°C water for 21 days.

A performance specification should be implemented to minimize the number and severity of shrinkage cracks. This specification should include the following points:

- LMC is to be moist cured for a minimum of 2 days to allow the polymer film to form while MSC is to be moist cured for a minimum of 7 days to reduce short-term shrinkage.
- Based on the permeability results for cracked and uncracked specimens presented in Appendix E, the average permeability for both LMC and MSC overlays tested at 28 days as outlined above should be less than or equal to 800 coulombs with a 95% UCL of less than or equal to 1200 coulombs to minimize shrinkage cracking.
- Unrestrained average shrinkage (ASTM C157) of LMC and MSC at 28 days of drying is to be less than or equal to 0.04% with a 95% UCL of less than or equal to 0.05%.

### Recommended Practice Based on Other Research

The performance specification should also include the following:

- The air content for LMC should be  $5\% \pm 2\%$  and for MSC should be  $6\% \pm 2\%$ .
- The compressive strength of both LMC and MSC overlays should be at least 34.5 MPa at 28 days.
- Bond strength for both LMC and MSC overlays should be at least 1.03 MPa (150 psi) at 28 days.
- Any delaminations found using the chain drag method at 28 days should be removed and replaced.
- Any areas exhibiting pattern cracking at 28 days should be removed and replaced.
- Any areas exhibiting greater linear crack frequency than  $0.39 \text{ m/m}^2$  at 1 year should be removed and replaced.

## **APPENDIX A: LITERATURE REVIEW**

## LATEX-MODIFIED AND MICROSILICA CONCRETE SHRINKAGE LITERATURE REVIEW

### Introduction

Shrinkage is a three-dimensional deformation of concrete that results in an overall reduction in volume. Typically, the shrinkage of a concrete specimen is expressed as a linear strain since one of the dimensions is generally significantly larger than the other two and “the effects of shrinkage are greatest in the largest dimension” (Aïtcin, et al, 1997). As these internal strains increase, so does the potential for cracking (Shah, et al, 1998). Cracks may ease the ingress of chloride ions to the reinforcing steel. This, in turn, may lead to an increase in the rate of corrosion of the steel and a further reduction in strength.

There are four types of shrinkage: plastic shrinkage, autogenous shrinkage, drying shrinkage, and carbonation shrinkage (Aïtcin, et al, 1997). The total shrinkage can be measured under either restrained or unrestrained conditions. This review of the literature will examine the different types of shrinkage, specifically with respect to latex-modified concrete (LMC) and silica fume (microsilica) concrete (SFC), and is restricted to the past twenty-five years.

### Plastic Shrinkage

#### Introduction

Plastic shrinkage is caused by water loss from the surface of concrete within a few hours of placement while the concrete is still plastic and before it gains any significant strength (Soroushian and Ravanbakhsh, 1998). This loss is generally due to evaporation to the atmosphere, which depends upon temperature, relative humidity, wind velocity, and the rigidity of the fresh concrete (Aïtcin, et al, 1997). Plastic shrinkage will occur if conditions exist which permit “a faster rate of evaporation of water from the surface of fresh concrete than the water replaced by bleeding from the concrete underneath” (Malhotra, et al, 1987). Therefore, any admixture that reduces bleeding increases the risk of plastic shrinkage occurring. The effects of surface evaporation are amplified by the “[s]uction of water from concrete by the sub-base or formwork materials or due to the internal consumption of water during hydration” (Soroushian and Ravanbakhsh, 1998).

#### Latex-Modified Concrete

Styrene-butadiene latexes are often used in bridge deck overlays to increase resistance to chloride intrusion. Latexes used in latex-modified concrete (LMC) overlays contain surfactants to prevent coagulation; these surfactants also function as water reducers in the concrete (Kuhlmann, 1990). Since this results in a lower water-cement ratio (w/c), less water is available for bleeding, increasing the probability of plastic shrinkage occurring.

In Virginia, a study conducted by Michael Sprinkel (1984) of the Virginia Highway Transportation Research Council of twelve bridges with LMC overlays showed that plastic shrinkage in LMC is more likely than in A4 concrete. The overlays studied ranged in age from new to thirteen years. Since LMC has a lower w/c than A4 concrete, less water is readily available to forestall plastic shrinkage. Of the bridges studied, only two had significant amounts

of shrinkage cracking, from which Sprinkel surmised that if the proper care is taken at the time of placement, plastic shrinkage cracking in LMC overlays is preventable (Sprinkel, 1984).

In an examination of LMC overlaid bridges in Washington state, Khossrow Babaei and Neil Hawkins (1990) performed “[d]etailed field and laboratory studies...on twelve selected concrete overlaid bridge decks (six LMC and six LSDC [low-slump dense concrete]) in Washington to determine performance and where unforeseen problems had occurred in the overlays’ performance to recommend modifications to design and construction procedures”. The LMC overlays they studied during the summer of 1986 had a nominal thickness of 38 mm (1.5 in.), an average age of 5 years, and experienced an average daily traffic (ADT) volume of approximately 7000 vehicles. Field investigations determined that “[t]he maximum amount of cracking the in LMC overlays was 40% of the deck area,” but cited nationwide inspections that indicate that LMC overlays “have the potential to develop 100% surface cracking”. They believed plastic shrinkage to be the main cause of the majority of the cracks. In cores taken from newly placed LMC overlays cracks only extend 10 mm ( $\frac{3}{8}$  in.) to 19 mm ( $\frac{3}{4}$  in.) deep, while in the test overlays cracks reached at least as far as the bonded surface. They felt this shows that the cracks formed during the plastic state and increased in size over time due to repeated live and environmental loading (Babaei and Hawkins, 1990).

#### **Silica Fume Concrete**

As with latex, silica fume (SF) “induces a tendency for plastic shrinkage,” although in the case of SF this is due to the fineness of the material (Ozyildirim, 1987). The fineness increases the water demand, leaving less free water to evaporate and thus is more susceptible to plastic shrinkage than conventional Portland cement concretes (PCCs). In fact, SFC overlays generally do not bleed, which increases the likelihood of plastic shrinkage (Luther, 1993). Research conducted to date indicates that SFC is most vulnerable to plastic shrinkage just prior to initial set (Malhotra, et al, 1987; Luther, 1993; Khayat and Aitcin, 1993).

#### **Prevention/Reduction**

Proper curing techniques are essential to the prevention of plastic shrinkage cracking. Both LMC and SFC overlays need to be covered with wet burlap and plastic promptly after placement (Kuhlmann, 1990; Babaei and Hawkins, 1990; Sprinkel, 1984; Luther, 1993; Kuhlmann, 1991; Sprinkel, 1988).

According to Babaei and Hawkins (1990), plastic shrinkage cracks in LMC overlays can be kept to a minimum “by allowing a maximum evaporation rate of 0.73 kg/m<sup>2</sup>/h (0.15 lb/ft<sup>2</sup>/h) while placing the overlay” and using measures to reduce the rate of evaporation, including those listed below.

- Erecting wind barriers
- Shading the aggregate to keep it cool
- Using cold mix water, possibly by including ice
- Using fog nozzles to maintain a sheen of moisture on the concrete surface before curing (Babaei and Hawkins, 1990)

Kuhlmann (1991) agrees with Babaei and Hawkins on the maximum evaporation rate and includes the recommendation that the damp burlap and polyethylene film be placed closely behind the finishing operation. The film should be white to “minimize the solar heat gain” and resulting quick increase in the temperature of the fresh concrete, and it should be weighted to prevent being blown off the concrete. He further urges tight control of the amount of water in the mix, decreasing the maximum allowable evaporation rate to 0.10 lb/ft<sup>2</sup>/h, and revising the normal practice of damp curing for only one day to damp curing for two days instead, especially when the temperature and wind conditions are conducive to plastic shrinkage. Increasing the damp curing time will cause a slight expansion of the LMC overlay, putting the concrete into compression and decreasing the tendency towards plastic shrinkage cracking while having a negligible effect on compressive strength (Kuhlmann, 1991). On average, the typical LMC overlay is ready for traffic after four to seven days of total curing (Malhotra, 1987).

Luther (1993) recommends gently placing “dripping wet burlap” on each section of the SFC overlay immediately after texturing. If plastic is used, it is then placed on top of the burlap. Soaker hoses may then be strung under the plastic or, if no plastic is used, after every few strips of burlap. SFC needs to be wet cured for a minimum of two to seven days, although longer wet cure times are encouraged. Curing compounds and evaporation retarders can be useful, but are not a substitute for wet curing. Like Kuhlmann, Luther also recommends not allowing the evaporation rate to exceed 0.10 lb/ft<sup>2</sup>/h (1993).

### **Autogenous Shrinkage**

#### **Introduction**

Autogenous shrinkage, also known as self-desiccation or chemical shrinkage, takes place as a result of cement hydration and develops isotropically within the concrete mass (Aïtcin, et al, 1997). Jensen and Hansen (1996) define self-desiccation as the “lowering of internal relative humidity in a closed isothermal cement paste system” resulting from the “internal volume reduction associated with the hydration of portland cement.” The hydration process is a chemical reaction between Portland cement (PC) and water and the products of this reaction have less volume than the reactants. Autogenous shrinkage results from this self-desiccation in the following manner: water is removed from progressively smaller pores to allow hydration to proceed and this leads to self-desiccation, a reduction in the relative humidity of the pores in the hydrating concrete. As the pore size decreases, water tension increases, and these tensile stresses lead to shrinkage of the cement paste (Jensen and Hansen, 1996; Persson, 1997). Autogenous shrinkage can occur even in unloaded specimens (Persson, 1997) in the absence of water evaporation (Paillère, et al, 1989).

#### **Latex-Modified Concrete**

The literature search did not identify any articles published within the last twenty-five years that address the autogenous shrinkage of LMC.

## Silica Fume Concrete

Paillère, et al (1989) examined the effect of steel fiber addition on the autogenous shrinkage of concrete. The w/c, amount of superplasticizer, amount of fibers, and SF content of the test mixtures were varied. To prevent evaporation, every exposed surface of each specimen was covered with a product based on a synthetic resin. They found that concrete with a low w/c experienced high amounts of autogenous shrinkage, autogenous shrinkage caused rapid cracking in restrained SFC specimens, and steel fibers can increase time to cracking and help provide confinement after cracking. The researchers believed the large values of autogenous shrinkage experienced by high strength concretes were caused by “an intense self-desiccation of the cement paste component in these concretes, resulting from an extremely low w/c” (Paillère, et al, 1989).

De Larrard and le Roy (1993) studied the influence of mixture composition on the mechanical properties of high-performance concrete (HPC) containing SF. The reference concrete contained no admixtures or SF while all other mixtures included varying amounts of SF and superplasticizer. The w/c of the test mixtures ranged from 0.33 to 0.50. All specimens were sealed with two sheets of self-adhesive aluminum after demolding to prevent any moisture exchange with the environment. The specimens were stored in a controlled temperature room of  $20\pm 1^{\circ}\text{C}$  and measurements began at an age of 48 hours. By the age of 5000 hours, the reference concrete mixtures had autogenous shrinkage values of less than 50 microstrain compared to values ranging from 64 to 111 microstrain for all mixtures containing SF (de Larrard and le Roy, 1993).

Jensen and Hansen (1996) conducted research into autogenous deformation and change of the relative humidity in silica fume-modified cement paste. They varied the type of cement used as well as the amount of SF and the w/c. The researchers found that while all of the variations in mixture composition affected autogenous shrinkage, SF dosage had a “dominating influence.” A 10 percent addition of SF increased the autogenous deformation by 1000 microstrain after 2 weeks; however, an decrease in the w/c from 0.40 to 0.25 only increased the autogenous deformation by 200 microstrain in the same amount of time (Jensen and Hansen, 1996).

Persson (1997) examined self desiccation of HPCs with w/c varying between 0.25 and 0.38. He measured specimens for autogenous shrinkage from one day to two years of age. He found that decreasing the w/c and increasing the SF content had the greatest effect on autogenous shrinkage (Persson, 1997).

In a later study by Persson (1998), he conducted further research on the shrinkage of HPC. All mixture proportions were varied and w/c ranged from 0.25 to 0.38. Specimens were insulated by 2 millimeters of butyl rubber clothing and stored in a controlled environment of  $20^{\circ}\text{C}$  and 55% relative humidity. Beginning at an age of one hour and continuing until an age of three to four years, autogenous shrinkage measurements were taken by mechanical devices. Concretes with the lowest w/c and highest SF replacement experienced the greatest amounts of autogenous deformation over time (Persson, 1998).

## **Prevention/Reduction**

Autogenous shrinkage can be reduced by limiting the amount of SF replacement, increasing the w/c, and by ensuring proper curing of the concrete. According to Aïtcin, et al (1997), “[t]he development of autogenous...shrinkage can be delayed by wet curing, and prolonged curing can help avoid the development of cracking.” Wet curing should commence as soon as hydration begins, especially with rapid-hardening cements, and should continue until the concrete has developed the necessary tensile strength to resist cracking (Aïtcin, et al, 1997).

## **Drying Shrinkage**

### **Introduction**

Drying shrinkage occurs in the hardened concrete as free water evaporates from the capillary pores. Capillary tension theory explains that “drying shrinkage is caused by the capillary tension occurring [sic] in the moisture existing in the pores in the cement gel” (Tazawa and Yonekura, 1987). The smaller the pore, the greater the tension is in the pore water. As this tension increases, it is harder for the water to evaporate. Thus, free water evaporates from larger pores first and “the loss of water is progressive and proceeds at a decreasing rate” (Aïtcin, et al, 1997). The rate of progression of drying shrinkage depends on the ratio of volume to exposed surface area of the concrete specimen. Drying shrinkage decreases as this ratio increases (Ohama, 1995).

### **Latex-Modified Concrete**

In Sprinkel’s (1984) examination of LMC overlays in Virginia, he found that “the 28-day shrinkage for LMC is about twice the 0.025% typically exhibited by A4 concrete.” Of the four sets of samples prepared in 1983, measurements indicated that drying shrinkage resulted in length changes varying from 0.042 percent to 0.056 percent, showing that LMC overlay concrete is subject to more drying shrinkage than is conventional concrete (Sprinkel, 1984).

Another investigation conducted by Sprinkel (1988) compared the physical and mechanical properties of a high early strength latex modified concrete (LMC-HE) overlay with those of a standard LMC overlay. The LMC-HE mixture contained more cement with a lower w/c than the LMC mixture. Specimens for shrinkage testing were moist cured for two weeks and then were dried in air in the laboratory. Tests were conducted on 6 to 8 prism specimens measuring 76 mm by 76 mm by 286 mm. At 28-days, the drying shrinkage values of the LMC-HE averaged 0.042 percent, which is lower than that of LMC but still significantly higher than the drying shrinkage of A4 concrete (Sprinkel, 1988).

Although Babaei and Hawkins (1990) determined that the majority of the cracks found in their study of Washington state bridge deck overlays were caused by plastic shrinkage, their research showed that drying shrinkage could be significant. They found that “in spite of the small amount of water in its mix, the long-term shrinkage of LMC is high, especially in the first two weeks after construction.” This shrinkage would have little effect on newly constructed bridge decks since the shrinkages of deck and overlay are compatible; however, placing a new

overlay on an existing bridge deck that has already shrunk may cause cracking in the shrinking LMC overlay (Babaei and Hawkins, 1990).

According to Kuhlmann (1991), the drying shrinkage of LMC is controlled by the w/c of the mixture. He stressed the importance of ensuring excess water is not added to ensure that an LMC mixture will have the same shrinkage characteristics as a conventional concrete mixture with the same w/c (Kuhlmann, 1991).

Ohama (1995) examined latex-modified mortar specimens that varied in size, polymer type, and polymer-cement ratios. Of the styrene butadiene latex emulsions studied, he found that increasing the polymer-cement ratio of a concrete tends to decrease the measured drying shrinkage at 28 days. The reduction in drying shrinkage may be attributable to the effects of surfactants and antifoamers in the emulsion (Ohama, 1995).

Folic and Radonjanin (1998) conducted experimental research on polymer modified concrete using a latex dispersion based on butadiene styrene rubber. The total fluid to cement ratio of the mixtures was held to a constant 0.43 with varying latex contents. Specimens were damp cured for one day, demolded, and further cured according to one of the four following regimes: air cure for 27 days, water cure for 2 days followed by 25 days of curing in air, water cure for 6 days followed by 21 days of air cure, or 27 days of water cure. They found that drying shrinkage decreased as the polymer-cement ratio increased. Also, specimens subjected to a combination of wet and dry cure evidenced less drying shrinkage (Folic and Radonjanin, 1998).

#### **Silica Fume Concrete**

Carette and Malhotra (1983) examined the mechanical properties, durability, and drying shrinkage of PCC incorporating SF. The research was conducted in three series. Series A examined mixtures of constant slump with an initial w/c of 0.64 and up to 30 percent replacement of cement by SF. Series B investigated mixtures with a constant water to cementitious materials ratio (w/c+s) of 0.40 and up to 30 percent replacement of cement by SF using a superplasticizer. Series C looked exclusively at the compressive strength development of Series B mixtures. Drying shrinkage specimens were cured under wet burlap for 24 hours, demolded, further cured in a water tank until an age of 28 days, and then were stored in air at  $23\pm 1^{\circ}\text{C}$  and  $50\pm 4\%$  relative humidity. Changes in length and weight were recorded for 84 days. The researchers concluded that “[t]he drying shrinkage of concrete incorporating silica fume is generally comparable to that of control concrete regardless of the w/c+s” (Carette and Malhotra, 1983).

Ozyildirim (1986; 1987) studied concrete containing SF for use in bridge deck overlays. Specimens had a w/c of either 0.35 or 0.40 and were moist cured for one month before storage in ambient laboratory air. Compared to control concrete mixtures not containing SF, the experimental mixtures had similar but lower drying shrinkage values at an age of 32 weeks (Ozyildirim, 1986; Ozyildirim, 1987).

Tazawa and Yonekura (1987) studied drying shrinkage and creep of concrete containing condensed silica fume (CSF). Specimens were subjected to one of two curing regimes,

specifically, standard and autoclave curing. Measurements were generally taken in air at 20°C and 50% relative humidity, although some were taken in water at 20°C. The w/c varied from 0.25 to 0.65 in order to cause variations in pore size to evaluate the effects of pore structure on drying shrinkage. Changes in length and weight were measured for 800 days. They found that conventional concrete specimens with w/c between 0.40 and 0.65 showed an increase in drying shrinkage strains with an increase of unit cement paste volume, but specimens with w/c of 0.25 and 0.30 demonstrated a decrease in drying shrinkage strains despite the large unit cement paste volume. Comparatively, all specimens containing CSF except those with a w/c of 0.65 had lower values for drying shrinkage strain, leading the researchers to believe that the “drying shrinkage of concrete is closely related not only to unit cement paste volume, but also to w/c and the existence of condensed silica fume” (Tazawa and Yonekura, 1987).

Kohno and Komatsu (1987) tested mixtures containing ground bottom ash and SF for drying shrinkage. Specimens were cured either conventionally, steam cured, or cured in an autoclave and subsequently stored at 20±1°C and 65±10% relative humidity. Measurements were taken using a microscope-type comparator. Their results showed that the drying shrinkage of concretes containing SF were about ten percent higher than that of conventional concrete, leading them to conclude that concretes containing SF tend to have greater drying shrinkage because water content has to be increased to obtain the same slump as a standard concrete mixture (Kohno and Komatsu, 1987).

Wolsiefer, et al (1995) examined the performance of concretes incorporating various forms of SF. Eleven different product forms of SF were used and the water to cementitious materials ratio (w/c+sf) varied between 0.22 and 0.40. All mixtures utilized a superplasticizer and an ordinary water reducer-retarder and, except for the concretes with a w/c+sf of 0.22, all mixtures were air entrained. Specimens were moist cured for either 7 or 28 days and drying shrinkage was measured at 448 days. The researchers found that the product form of the SF used did not have a significant impact on mechanical properties or durability. They found that regardless of product form, concretes containing SF had low drying shrinkage values of approximately  $500 \times 10^{-6}$  (Wolsiefer, et al, 1995).

Haque (1996) performed an experiment to study the strength development and drying shrinkage of high-strength concretes. His high-strength mixtures contained condensed silica fume (CSF) or a combination of CSF and either ground granulated blast furnace slag (GGBFS) or fly ash (FA) and were compared to conventional concrete specimens. Specimens were subjected to one of three different curing regimes: continuously cured in a fog room until testing, cured in a fog room for two days then moved to a control room until 24 hours before testing, or cured in a fog room for six days then moved to a control room until 24 hours before testing. The control room maintained a constant temperature of 23±2°C and 40±5% relative humidity. Twenty-four hours prior to testing, specimens were returned to the fog room “to negate skin effects and to bring all specimens to a standard level of moisture condition.” He found that the drying shrinkage of all mixtures tested varied between 480 and 640 microstrain at an age of 91 days. The addition of CSF tended to reduce drying shrinkage values; however, the further addition of either FA or GGBFS tended to increase drying shrinkage. The reduction of shrinkage in specimens containing only CSF was believed to be due to “the densification of the hydrated cement paste and the resultant slowing down of the water evaporation” (Haque, 1996).

Whiting, et al (2000) studied the cracking tendency and drying shrinkage of SFC for bridge deck applications, including both full-depth and overlay placements. The water to cementitious materials ratio (w/cm) varied between 0.35 and 0.45 for full-depth bridge deck mixtures and between 0.30 and 0.40 for overlay mixtures. Restrained and unrestrained shrinkage tests were performed. All specimens were moist cured for 18 to 24 hours and demolded. Restrained (ring) specimens then had polyethylene sheets affixed to the top surface with a silicone sealant while unrestrained (prism) specimens were cured in limewater. Overlay specimens spent three days in the limewater; full-depth specimens were cured for seven days in limewater. All specimens were stored in a controlled environment of  $23\pm 1.7^{\circ}\text{C}$  and  $50\pm 4\%$  relative humidity. The results showed that the overlay mixtures, despite having a lower w/cm, experienced more shrinkage than corresponding full-depth concrete mixtures, especially at later ages. The researchers attributed this to: “1) the higher paste content of these mixtures; and 2) their shorter moist curing time (3 versus 7 days).” Comparisons of time to first crack show that overlay mixtures are more likely to crack and tend to crack at earlier ages than full-depth mixtures. All the overlay specimens had cracked by an age of 28 days; less than half of the full-depth specimens cracked. Control specimens not containing SF cracked at an average age of 42 days. From these results, the researchers concluded that drying shrinkage values in concretes containing SF are very sensitive to changes in w/cm (Whiting, et al, 2000).

#### **Prevention/Reduction**

To reduce drying shrinkage, Aitcin, et al (1997) state that it is important to prevent evaporation of water from the concrete surface; thus, “an application of an impervious film is sufficient.” Both LMC and SFC benefit from additional curing time. Kuhlmann (1990; 1991) averred that LMC should be cured for two days, instead of one, to decrease the tendency to form shrinkage cracks. Folic and Radonjanin (1998) found that LMC needed to be subjected to a combination of wet and dry curing to produce optimum results and recommended a six-day period of curing in a high humidity environment followed by curing in dry conditions. This regime provides the requisite humidity for cement hydration and still allows the polymer membranes to form and harden (Folic and Radonjanin, 1998). Whiting, et al (2000) believed that because of the sensitivity of SFC mixtures to changes in the w/cm, extra care should be taken during construction that excess water not be added to such mixtures. In addition, they recommended limiting the amount of SF in a mixture to no more than eight percent by mass of cementitious materials and curing the mixture for seven days to reduce cracking resulting from drying shrinkage (Whiting, et al, 2000). Kohno and Komatsu (1987) also recommend the use of a water-reducing admixture or high range water-reducing admixture to lower the amount of drying shrinkage experienced by SFC.

## Carbonation Shrinkage

### Introduction

Carbonation is a well-understood expansive chemical reaction that occurs in the presence of moisture between the hydrated cement paste and the carbon dioxide in the air (Aitcin, et al, 1997). The American Concrete Institute (ACI) defines carbonation as the “reaction between carbon dioxide and calcium compounds, especially in cement paste, mortar, or concrete, to produce calcium carbonate” (ACI Committee 116, 1990). Researchers have found that, in addition to calcium hydroxide ( $\text{Ca}(\text{OH})_2$ ), carbonation reactions occur with calcium silicate hydrate (CSH), tricalcium silicate ( $\text{C}_3\text{S}$ ), and dicalcium silicate ( $\text{C}_2\text{S}$ ) (Claisse, et al, 1999). The presence of alkali ions causes a loss of cohesiveness in the concrete as a result of the carbonation reaction (George, 1983). The volume of the cement paste decreases as carbonation progresses (Soroka, 1979). This carbonation shrinkage is not well understood. One theory assumes “the precipitated calcium hydroxide crystals restrain the shrinkage of the cement gel.” Once these crystals dissolve and react with the carbon dioxide, the restrained shrinkage is released (Jensen and Hansen, 1996). Carbonation also affects drying shrinkage, and this effect “reaches a maximum at approximately 50% relative humidity” (Soroka, 1979).

### Latex-Modified Concrete

Kuhlmann (1990) published the results of an experiment in which LMC specimens were soaked in a sodium carbonate solution for a period of six months. The results showed that depth of carbonation of LMC increases with exposure time and decreases with an increase in the latex-cement ratio (Kuhlmann, 1990).

### Silica Fume Concrete

Wolsiefer, et al (1995) measured the depth of carbonation after 448 days in their examination of the performance of concretes containing various forms of SF. They found that the form of SF had no effect on the carbonation depth. The specimens with w/c+sf of 0.30, 0.35, and 0.40 experienced a depth of carbonation of 5 millimeters or less, while specimens with a w/c+sf of 0.22 did not exhibit carbonation. The researchers felt that five millimeters of carbonation was not significant (Wolsiefer, et al, 1995).

Persson (1998) examined carbonation as part of his experimental studies of HPC. His results showed that weight loss due to drying shrinkage ceased because of carbonation at an age dependent on the w/c and that the internal relative humidity remains constant after initiation of carbonation. Additionally, none of the specimens with a w/c less than or equal to 0.25 exhibited carbonation. His findings showed that carbonation is dependent on the w/c and the SF content. An HPC with a low w/c and high SF content had little or no carbonation, and consequently no carbonation shrinkage. He stated that although it was appreciably smaller than drying or autogenous shrinkage, carbonation shrinkage could still have a significant effect on durability (Persson, 1998).

### **Prevention/Reduction**

Maintaining a low w/c can reduce carbonation, and thus carbonation shrinkage (Kuhlmann, 1990; Wolsiefer, et al, 1995; Persson, 1998). For LMC, increasing the polymer-cement ratio also has a beneficial effect on carbonation (Kuhlmann, 1990). For SFC, carbonation may be reduced by increasing the amount of cement replacement by SF (Persson, 1998).

**APPENDIX C: AMBIENT LABORATORY AIR TEMPERATURE AND RELATIVE HUMIDITY**

Figure C1: Ambient Laboratory Air Temperature and Relative Humidity as a Function of Time

**APPENDIX D: COMPRESSIVE STRENGTH AND MODULUS OF ELASTICITY**

## FIELD MIXTURES

Field-cast compressive strength specimens were stored in the uncontrolled laboratory environment after the initial moist cure and adjacent to the shrinkage specimens. In addition, some of the field-cast specimens were stored in a moist room at 100% RH and 22°C. The compressive strength results from cylinders stored in the uncontrolled environment are designated “Dry Strength,” while the compressive strength results from cylinders stored in the moist room are designated “Wet Strength.” All the specimens used in modulus of elasticity testing were stored in the uncontrolled laboratory air.

### LMC Mixtures

**LABORATORY MIXTURES**

The cylinders cast for compressive strength testing from each of the laboratory mixtures were not stored in separate environments. The cylinders cast from LMC mixtures were all stored in ambient laboratory air after moist curing to allow formation of the polymer film. The cylinders cast from MSC mixtures were all stored in a controlled humidity environment with a RH of approximately 100% and temperature of 22°C.

Note: Laboratory mixtures were cast in two batches; the values above are the overall total of specimens cast.

**PATRICIA MICHELLE BUCHANAN**

Patricia was born in Portsmouth, Virginia, on September 7, 1978, to Ronald and Darlene Buchanan. She grew up in Frederick County, Virginia, and attended James Wood High School and Sherando High School. Tricia graduated from Sherando in 1996 first in her class. After high school, she attended Virginia Tech and graduated in 2000 with a Bachelor of Science degree in Civil Engineering. She then pursued a Master of Science in Civil Engineering at Virginia Tech. Upon completion of her graduate degree, Tricia will be working as a forensic engineer for Whitlock, Dalrymple, Poston, and Associates in Manassas, Virginia.
